and Research**

Dr. Roland A. Carlstedt is a licensed clinical and applied psychologist. He is the chairman of the American Board of Sport Psychology. Board certified in sport psychology (ABSP) and clinical psychophysiology and biofeedback (BCIA), Dr. Carlstedt earned his doctorate in psychology with honors from Saybrook Graduate School and Research Center (with emphases in health and sport psychology and psychophysiology) in San Francisco, under the renowned personality psychologist and behavioral geneticist Dr. Auke Tellegen of the University of Minnesota. He has completed postdoctoral continuing education in psychiatric neuroscience through Harvard Medical School, along with training in the joint Massachusetts General Hospital-Massachusetts Institute of Technology-Harvard Medical School Athinoula A. Martinos Center for Biomedical Imaging Functional Magnetic Resonance Imagery (fMRI) Visiting Fellowship and NIH-funded Multi-Modal Brain Imaging programs. Dr. Carlstedt is a member of the Harvard Medical School Postgraduate Association and Massachusetts General Hospital Psychiatry Academy. He is also a research fellow in applied neuroscience with the Brain Resource Company, sits on the advisory board of BioCom Technologies, and is the clinical and research director of Integrative Psychological Services of New York City. Dr. Carlstedt was the recipient of the American Psychological Association's Division 47 2001 Dissertation Award. His research has been published in *Biofeedback*, *Cortex*, *Brain and Cognition* and the *Journal of the American Board of Sport Psychology* and various academic books. Dr. Carlstedt consults with numerous athletes, teams and sports organizations worldwide including the Harlequins Professional Rugby Union Team (London, U.K.) and the Polish Tennis Federation. His ongoing research includes the Universal Clinical Trial, neuropsychophysiological investigations of the high-risk model of threat perception, the dual-placebo-nocebo effect and in-vivo qEEG and HRV functioning in athletes and clinical contexts.

The author and the publisher of this Work have made every effort to use sources believed to be reliable to provide information that is accurate and compatible with the standards generally accepted at the time of publication. Because medical science is continually advancing, our knowledge base continues to expand. Therefore, as new information becomes available, changes in procedures become necessary. We recommend that the reader always consult current research and specific institutional policies before performing any clinical procedure. The author and publisher shall not be liable for any special, consequential, or exemplary damages resulting, in whole or in part, from the readers' use of, or reliance on, the information contained in this book. The publisher has no responsibility for the persistence or accuracy of URLs for external or third-party Internet Web sites referred to in this publication and does not guarantee that any content on such Web sites is, or will remain, accurate or appropriate.

SECTION I

Conceptual and Methodological Issues, Perspectives, and Directions in Clinical Practice and Research

Chapter 1	Conceptual, Methodological, and Practice Foundations of Integrative Evidence-Based Clinical Research, Diagnostics, and Intervention	1
	<i>Roland A. Carlstedt</i>	
Chapter 2	Critical Thinking and Evidence-Informed Practice as Guides to Clinical Decision Making	17
	<i>Eileen Gambrill</i>	
Chapter 3	Clinical Trials: A Primer for Clinicians	33
	<i>Itay Perlstein and Eric J. Olson</i>	
Chapter 4	The Implementation of Empirically Supported Psychotherapy: Practice Foundations	59
	<i>Stevan Lars Nielsen, Michael J. Lambert, David W. Smart, John Okiishi, Richard L. Isakson, Tyler Pedersen, and Dianne L. Nielsen</i>	

SECTION II

**Primary Higher-Order Mediators in Preventive
Medicine and Mental Health: Predispositions,
Psychophysiological Development, and
Behavioral Tendencies**

Chapter 5	Behavioral Genetics.	81
	<i>Anna A. E. Vinkhuyzen, Sophie van der Sluis, and Danielle Posthuma</i>	
Chapter 6	Sleep Medicine and Sleep Disorders	95
	<i>Maxime Bonjean, Carl Stepnowsky, Thien Thanh Dang-Vu, Terrence J. Sejnowski, and Pierre Maquet</i>	
Chapter 7	Evidence-Based Clinical Management of Behavioral Nutrition.	153
	<i>Janet Colson</i>	
Chapter 8	Exercise in Preventive Behavioral Medicine: The Disconnected Values Model.	177
	<i>Mark H. Anshel</i>	
Chapter 9	Integrative Diagnosis and Intervention: The High-Risk Model of Threat Perception Revisited	191
	<i>Roland A. Carlstedt</i>	

SECTION III

**Select Disorders in Clinical and Health Psychology,
Psychiatry, and Behavioral Medicine**

Chapter 10	Eating Disorders: Advances in Treatment and Management	215
	<i>Anthea Fursland, Hunna J. Watson, Bronwyn Raykos, Anna Steele, and Sue Byrne</i>	
Chapter 11	Emotional Intelligence and Substance Abuse: An Integrative Approach to Assessment and Treatment	245
	<i>Denise Fortino</i>	

Chapter 12	Affective Disorders: Bridging the Gap Between Efficacy and Practice	281
	<i>Hunna J. Watson, Peter M. McEvoy, Laura M. Smith, Lisa M. Saulsman, Bruce N. C. Campbell, and Paula R. Nathan</i>	
Chapter 13	Anxiety Disorders in Children and Adults: A Cognitive, Neurophysiological, and Genetic Characterization.	309
	<i>Andrei C. Miu and Laura Visu-Petra</i>	
Chapter 14	Post-traumatic Stress Disorder	353
	<i>Gina Manguno-Mire and C. Laurel Franklin</i>	
Chapter 15	Attention-Deficit (Hyperactivity) Disorder	379
	<i>Stephan Bender, Tobias Banaschewski, and Franz Resch</i>	
Chapter 16	Evidence-Based Clinical Management of Obsessive-Compulsive Disorder.	411
	<i>Hunna J. Watson, Rebecca A. Anderson, and Clare S. Rees</i>	
Chapter 17	Integrative Pain Medicine.	443
	<i>Jeanne Taylor Hernandez</i>	
Chapter 18	Quantitative Electroencephalography in the Assessment and Rehabilitation of Traumatic Brain Injury.	463
	<i>Kirtley E. Thornton and Dennis P. Carmody</i>	
Chapter 19	Personality Disorders	509
	<i>Maria Poston, Kara Liebling Kahan, and Dawnelle Schatte</i>	
Chapter 20	Tourette Syndrome: A Model of Integration.	549
	<i>Elia Abi-Jaoude, David Kideckel, Robyn Stephens, Myriam Lafreniere-Roula, Judith Deutsch, and Paul Sandor</i>	
Chapter 21	Schizophrenia.	589

Foreword

The word “integrative” is being used in a growing number of sectors in the crowded, specialized health care landscape.

The brain is a highly interconnected, dynamic adaptive system. The specialized, reductionist medical model that so successfully found single treatments to solve specific body problems is all too often failing in brain-related disorders.

As a consequence, clinicians are increasingly embracing the complexities of brain function and the enormous individual variation produced by the interactions of each person’s biology and experiences, across the life span.

A more personalized evidence-based approach is emerging in a paradigm shift that is challenging the simplistic, specialized, one-size-fits-all approaches to treatment that are not tailored to each individual. This new paradigm of integrative evidence-based personalized health care is further driven by the harsh reality that not only are many treatments simply not working for a significant percentage of patients, but there is a high loss of compliance and side effects when the solutions are not well matched to an individual patient. Moreover, solutions in separate, specialized clinical disciplines are often approached in a trial-and-error manner that has led to over-servicing, an escalation of costs, and inefficiency in the health care system. As a result of the recognition of the need for a more realistic integrative approach to health care, coupled with the significant morbidity and costs of specialized reductionist approaches, more integrative, evidence-based health care is being explored across the brain-body clinical landscape.

Many practitioners, educators, clinicians, and researchers in allied mental health and behavioral medicine want to provide an evidence-based personalized health care service. But *how* to do so is unclear.

That is what makes this book timely and important. It provides a road map to doing so.

Sections 1 and 2 set the groundwork for how to get there. These sections inspire the reader and discuss the requisite critical thinking, conceptual models, methods, and interventions. The remaining three sections provide integrative exemplars across the continuum of disability and well-being that point the way forward to a personalized evidence-based integrative health care.

This book reflects the courage of its contributors to rise above the vested interests of the specialized stakeholders in health care. They explore the inevitable intersections between brain disorders, their myriad comorbidities and the interactions with nutrition, exercise, sleep regulation, stress recovery, conventional

medication, biofeedback, neurofeedback, and other potentially useful therapies.

Crucially, this dynamical complexity is embraced with the explicit goal of moving toward a disciplined personalized evidence-based integrative health care—the right pattern of solutions, for the right person, at the right time.

*Dr. Evian Gordon
Adjunct Associate Professor, University of Sydney,
Sydney Medical School, Founding Director of the
Interdisciplinary Brain Dynamics Center at Westmead
Hospital, New South Wales, Australia, and CEO
and Chairman of Brain Resource Limited*

Preface

This is a book that was written by clinicians for clinicians, students, and future practitioners in training. It was designed to foster interdisciplinary understanding, information sharing, and the use of integrative approaches to patient assessment, treatment, and efficacy studies. The book was made necessary by the fact that mental health practice has become increasingly specialized, with the majority of practitioners, especially those in private practice, working in relative isolation and in the context of unidimensional assessment and intervention paradigms that may no longer meet the gold standard for patient care or client services. Clinicians tend to practice the way they were trained and often go through an entire career steeped in an assessment and intervention approach that may be antiquated and even obsolete or needs to be augmented or amended with the best evidence-based practices. While many practitioners would welcome the opportunity to update their clinical approaches, most are mired in the realities of surviving as a practitioner. Few have the time necessary to keep up with advances in the numerous subdomains of psychology, psychiatry, and behavioral medicine. In the end we all suffer from this state of affairs, especially patients, who frequently do not receive the highest standard of care available.

Consequently, a road map is needed, a blueprint for an integrative clinical psychology, psychiatry, and behavioral medicine that is designed to disseminate vast amounts of critical emerging research in an efficient and understandable manner, as well as expose practitioners to sophisticated methods and procedures that need to be integrated into *all* clinical practices, regardless of orientation or specialty.

The psychoanalyst needs to be aware that advanced brain-imaging techniques are revealing things that appear reconcilable with parts of Freudian theory that have been previously discounted, yet realize that potent procedures exist that can immediately address and ameliorate symptoms, irrespective of their supposed etiology. Psychiatrists need to know about practices being used by psychologists who are demonstrating, for example, that heart-rate variability biofeedback may be a viable alternative for treating anxiety, as well as depression in patients who cannot safely tolerate psychotropic medications, or that neurofeedback may be the modality of choice for treating ADD in select individuals. Conversely, many psychologists and psychotherapists are not that familiar with the neurochemistry of psychotropic medications, leading many to foster an often radical bias against certain drugs that have been shown to be

highly efficacious. Cardiologists need to be made aware of alternative evidence-based psychological interventions that may help alleviate refractory functional arrhythmias that frustrate patients. Virtually all practitioners need to consider issues of ecological validity and the temporal dynamics of an intervention or longitudinal impact of a treatment before marrying themselves exclusively to a method of psychotherapy. Sophisticated assessment and monitoring methods are capable of revealing things that previously were unobservable, including qEEG and in-the-field ambulatory wireless monitoring of psychophysiological processes.

These are a few of the many examples that this book will discuss—information and methods that are critical to optimal patient care but are not being adequately disseminated across clinical specialties.

Leaders and experts from numerous relevant practice domains have been recruited to share their knowledge, methods, and research in a quest for integrative practice. This book consolidates cutting-edge procedures, research, and potent data in a compendium that will give practitioners of most persuasions and training backgrounds practical insight into how to provide best evidence-based patient assessment and care. It was designed to foster an interdisciplinary approach to mental health care and facilitate a sorely needed move toward integrative practice in a era in which specialization pervades.

The book is divided into five sections. Section I is titled “Conceptual and Methodological Issues, Perspectives and Directions in Clinical Practice and Research.” It is a foundational section that not only critiques and challenges various prevalent approaches, paradigms, and practices in allied mental health fields but also advances ideas and perspectives that are intended to raise practitioner awareness of deficiencies in patient care and research that need to be remediated.

Section II is titled “Primary Higher Order Mediators in Preventive Medicine and Mental Health: Predispositions, Psychophysiological Development and Behavioral Tendencies.” This section is organized to reflect an integrative hierarchy of so-called primary higher-order factors that are hypothesized and in some cases have been shown to mediate psychophysiological symptoms and illness. Chapters in this section cover behavioral genetics, behavioral nutrition, sleep and sleep medicine, and exercise in behavioral medicine, along with models and hypotheses of mind-body medicine. Genetics, nutrition, sleep, exercise, and specifically isolated personality, behavioral, and psychosocial factors that this book section will discuss can be considered primary-higher order factors and mediators in both the disease and disorder equation and their amelioration and prevention.

In Section III, titled “Select Disorders in Clinical and Health Psychology, Psychiatry and Behavioral Medicine,” a wide array of commonly encountered disorders in allied mental health fields are presented from an integrative perspective. A goal of this portion of the book is to educate clinicians about topics (disorders, assessments, and procedures) that they may not be that familiar with or specialize in, so as to illuminate diagnostic strategies and treatment options. While this section is not exhaustive, it contains a representative cross-section of afflictions that are encountered in clinical and health psychology, psychiatry,

and behavioral medicine. These chapters should be read cognizant of the critical perspectives and methodological approaches and suggestions that are presented in Sections I and II. The discussed disorders should be contemplated in the context of emerging theory and research that to a certain extent call into question various accepted standard operating procedures, especially as they pertain to clinical practices and findings that, although still remaining equivocal at best, pervade.

Section IV is titled “Select Interventions in Clinical Practice.” In this section a wide variety of treatment modalities are presented, including commonly used approaches such as psychotropic intervention and cognitive-behavioral therapy. In addition, emerging procedures that warrant further scrutiny and use are featured in an attempt to raise awareness of methods that are becoming viable alternatives and in some cases central to ameliorating symptoms and improving physical and mental health. Such interventions include hypnosis, meditation, bio- and neurofeedback, sleep therapy, methods in behavioral cardiology, exercise psychotherapy, and transcranial magnetic stimulation.

Finally, in Section V, titled “Integrative Multimodal Assessment and Intervention,” clinical diagnosis and treatment are integrated in the context of a field-tested protocol that practitioners are encouraged to consider and apply on varying levels. A universal clinical trial project that allows practitioners, especially those who are in private practice, to contribute to and access a developing clinical database on mind-body predictor and outcome measures is advanced.

Acknowledgments

The origins of my quest for integrative clinical research and practice can be traced back to my graduate school days at Saybrook Graduate School and Research Center, where I had the good fortune of being exposed to some of the most brilliant minds in health psychology and behavioral medicine, including Ian Wickramasekera, Stanley Krippner, and Eugene Taylor. This institution has been at forefront of the integration of the mind and body and has become a think tank that has generated numerous cogent and provocative theories, ideas, and procedures that are making their way into the broader realm of mainstream allied mental health care, medicine, and clinical research. Saybrook has attracted many visiting and distinguished consulting faculty and scholars, including the late Michael Mahoney, a pioneer in cognitive-behavioral theory, and Auke Tellegen of twin studies and MMPI fame. I was mentored by both of these individuals, and Dr. Tellegen chaired my dissertation committee. The result of my efforts, which can in part be attributed to the guidance of the above individuals, was an American Psychological Association (Division 47) dissertation award. This work looked at components of Dr. Wickramasekera's high-risk model of threat perception (one of the first integrative models of mind-body functioning) in the context of athletes. The findings that I generated and the practical utility and predictive potency of this model have since guided my clinical practice and research and led to the conceptualization of this book. In an attempt to further advance, extend, and amend the high-risk model of threat perception, I sought to better establish its construct validity, primarily through multiple in-vivo longitudinal single-case neuropsychophysiological investigations of patients, clients, athletes, and performers. In this pursuit, I encountered Evian Gordon of the University of Sydney. He is CEO and chairman of the Brain Resource Company. He published the first book on *Integrative Neuroscience* (2000) and is a true visionary and integrationist in the field of applied neuroscience. BRC has set up the largest standardized international brain database in the world (which is available to independent scientific investigations at <http://BRAIN.net.net>). The Brain Resource Company also provides brain-related health care and behavioral change services to the largest health insurance company in the United States. Dr. Gordon's support has been invaluable in helping me develop a database of athlete and patient neurocognitive performance. I also was able to obtain further training in applied and clinical neuroscience through visiting fellowships at Massachusetts General Hospital–MIT–Harvard Medical School's Martinos Center for Biomedical Imaging under Robert Savoy, who, along with

his world-class faculty, provided me with additional insight and direction in my exploration of the brain-mind-body integration in clinical and performance contexts. I have also been influenced by Arne Dietrich of the American University in Beirut, whose transient hypofrontality hypothesis is providing new explanatory directions for a host of prefrontal-frontal brain lobe-based cognitive, performance, and clinical phenomena. Finally, I'd also like to thank Itay Perlstein, a distinguished clinical scientist, for his time and advice in matters of study design and advanced data analysis.

The above individuals and institutions have allowed me to put it all together in this book, a vehicle for disseminating high-quality information, emerging ideas, theories, procedures, research findings, and especially the integrative message. Of course, without the commitment of authors who essentially donated their valuable time to contribute chapters to this book, this work would not have been possible and I thank them. Likewise, I must acknowledge Phil Laughlin, a former senior editor at Springer Publishing, for his support and patience relative to this book project.

Conceptual, Methodological, and Practice Foundations of Integrative Evidence-Based Clinical Research, Diagnostics, and Intervention

Roland A. Carlstedt

CLINICAL RESEARCH: FOUNDATIONS OF PRACTICE?

For the most part, clinical research on interventions and resultant diagnostic and treatment recommendations have emanated from well-funded and well-staffed investigations at the institutional level. Findings are subsequently disseminated to practitioners in hopes that frontline therapists will actually acknowledge the data and follow a protocol in strict accord with empirically established guidelines. Although empirically validated treatment should drive clinical applications, the reality is that few practitioners strictly adhere to scientifically based protocols or engage in outcome studies to assess the efficacy of the interventions that they are utilizing (Barber, Mercer, Krakauer, & Calvon, 1996; Wilson, 1997). This is understandable, considering the practical constraints, financial realities, and methodological

requirements associated with systematic or controlled approaches to psychotherapy. In the context of private or small group practices, it can be difficult to adhere to the rigorous demands of a scientifically derived intervention protocol and assessment model. This presents a problem for researchers seeking to generalize findings and protocols to the real world of clinical practice. When a sufficient number of practitioners do not use certain protocols, it is difficult to concurrently validate or replicate their utility and substantiate their efficacy.

Since the essence of replication or validation is control, it is imperative that the “average” practitioner be given the tools and support necessary to participate in empirically validated approaches to treatment. However, this is easier said than done. Getting clinicians to subscribe to empirically validated or higher-level evidence-based treatment protocols is made difficult not only by clinical realities but also by practitioner perceptions and

beliefs regarding the validity and efficacy of supposed gold-standard research findings and resulting recommendations (Altman, 1999). Should practitioners trust and solely rely on information, findings, and advice that emanate from prestigious and influential research institutions and laboratories? To what extent are data and research findings reliable and deemed to be of such high quality that an intervention or diagnostic battery can be considered unequivocal and should be universally mandated (Boisaubin, 1995)? One could argue that most clinical research is inherently flawed and incapable of rendering absolute conclusions that lead to the adoption of intervention protocols, especially in the domain of mental health and psychotherapy. Clinicians holding such contrarian perspectives are also likely to practice in an eclectic manner, perhaps, and rightly so, in light of the complex nature of treating psychological and psychiatric disorders and the constantly changing landscape of clinical research that has not withstood the test of time and replication.

So what can be done to advance integrative evidence-based and empirically validated approaches to clinical diagnostics and intervention? A first step is to address specific conceptual, methodological, and statistical issues that are central to our understanding and misunderstanding of clinical research findings. Awareness of their potential impact on the validity and reliability of assessment and treatment procedures is critical if we want to make clinical research more integrative and cognizant of oversights and methodological problems that too often are discounted as trivial or unmanageable in the quest to make and announce the next big discovery.

Some of these issues are addressed next. Thereafter, current clinical practices are critiqued, and recommendations are provided on how to better integrate research and practice within a practitioner-based integrative clinical protocol designed to advance best practices in a unified manner, irrespective of a practitioner's clinical orientation or specialty.

CONCEPTUAL ISSUES: PREMATURE CONCLUSIONS AND FAULTY ASSUMPTIONS

While a plethora of research has implicated numerous psychological and biological factors in the mental health equation, many of these and other variables have to a large extent been investigated independently, and not in the context of more all-encompassing multifactorial and multivariate integrative models. This has on occasion

led to the release of findings on singular measures that have not withstood the test of time or replication with new research supplanting the old. Variables that were once seen as prominent are relegated to relative obscurity as they are replaced by other factors that in the end may be found to be just as tenuous as their predecessors in regard to their predictive validity. Moreover, root mediators or primary higher-order factors that potentially underlie constructs or measures that have been independently associated with various psychological disorders, diseases, and symptoms and their relationship to etiology, morbidity, and intervention efficacy often go unnoticed and uninvestigated.

For example, attention-deficit/hyperactivity disorder has been studied from various perspectives, including medical/pharmacological, neuropsychophysiological¹ and behavioral orientations (Jensen et al., 2001; Rossiter & LeVaque, 1995). Although psychiatrists and medical researchers have primarily focused on the neurobiology and pharmacological treatment of ADHD, they have generally failed to adequately consider psychological individual differences and behavioral factors that have been conceptually implicated in the development, onset, and treatment of various mental disorders (including ADD), and they have overemphasized psychotropic interventions (Goldman, Genel, Bezman, & Slanetz, 1998).² This may be attributable to their overconfidence in recent research findings on the neurochemistry/neurophysiology of ADD and the alleged efficacy of certain psychotropic medication. As a result, medical researchers and physicians may tend to view test participants and patients as homogeneous and assume that specific brain responses are consistently exhibited across situations, settings, and tasks as a function of a disorder and the medication used to treat it (Berger, Dor, Nevo, & Goldzweig, 2008). The consensus that specific universal brain functioning parameters underlie ADD at baseline and during specific performance contexts has led to the pervasive belief that this disorder can be best treated by manipulation of an afflicted individual's

1. The terms "neuropsychophysiological" and "mind-body" will be used interchangeably. They refer to brain-mind-body integrative neuropsychological, psychophysiological, neurophysiological, psychological, and behavioral processes and systems that are manifested in response to stimuli or exert an effect on health-related outcome measures.

2. This is to be expected, just as a psychotherapist is more likely to address mental disorders psychologically and not pharmacologically due to the inherently disparate training paths that prepare practitioners, despite the fact that physician and non-physician clinicians often treat the same populations and illnesses.

brain at the level of the cell pharmacologically (Berridge et al., 2006).

INDIVIDUAL DIFFERENCES AND VARIABILITY IN OUTCOME

These assumptions may be faulty, and what is frequently overlooked in the recruitment of participants for pharmacological/biomedical clinical trials are unique psychological individual differences factors that may actually affect or help suppress symptoms and response tendencies that alter alleged universal neurochemical/neurophysiological signatures of ADD (Polanczyk et al., 2008), especially when more sensitive micro-level dependent/criterion measures are incorporated into the design of a study, which usually is not the case in drug trials (Lubar, Swartwood, & Timmerman, 1995).³ For example, clinical case studies exist that have revealed levels of diffuse, elevated delta-wave electroencephalographic (EEG) activity at baseline under eyes-open test conditions in highly accomplished individuals (e.g., elite athletes and business leaders) that could be considered abnormal and of neurological significance.⁴ By contrast, these same individuals, when assessed under atypical baseline conditions, for example, outside a laboratory/office, and prior to a salient task or stimulus of interest (such as a tennis match or psychotherapy session), exhibited quantitative electroencephalographic (qEEG) profiles that were consistent with heightened attention and physiological reactivity (e.g., increases in diffuse beta-wave activity) and could be considered normal or even performance facilitative (Carlstedt, 2008). This finding, while requiring replication on a larger scale, suggests that all baseline stimulus conditions will not have the same impact across individuals and may lead to false-positive ADD diagnoses and may be mediated by individual differences.⁵

3. Outcome measures in drug trials are usually more global in nature, with, for example, longitudinally constrained symptom or disease attenuation (criterion/dependent variable) as a function dosage (predictor/independent variable).

4. Delta waves are seen during deep sleep; abnormal amounts in an eyes-open test condition are considered abnormal and indicative of underlying brain dysfunction (Andreassi, 1995).

5. Carlstedt (2008) has proposed that atypical manifestations of excessive theta and delta waves in highly functional and successful individuals serve an adaptive purpose by conserving cortical resources for when they are needed the most, namely, when the individual encounters specific situations and tasks that demand peak performance or responses. This can lead to false-positive diagnoses of ADD, depression, and other cognitive processing disorders.

A failure to control for individual differences variables will not necessarily statistically negate or call into question the efficacy of a particular psychotropic agent that was tested in a specific setting or stimulus situation that is known to generate symptoms of a disorder. It may, however, call into question a drug's actual or practical clinical effectiveness at the level of the single case if expected target symptoms or performance scores are not manifested by or do not result from stimulus conditions under which a drug is or is not tested. For example, hypnotic susceptibility and neuroticism may interact to modulate baseline levels of autonomic nervous system (ANS) activity to the extent that changes in outcome (e.g., effect of a drug on Test of Variables of Attention, or TOVA, score) are mitigated or paradoxical performance decrements are seen in select study participants. Although this is a hypothetical example that needs to be empirically tested, virtually all investigations contain variability that cannot be fully accounted for on the basis of the limited number of predictor/independent variables that are considered in the original design of a study. Consequently, it stands to reason that individual difference variables, including psychological traits and behaviors, may account for significant amounts of the variance that cannot be explained solely on the basis of unidimensional study designs that only take into account one predictor/independent and one outcome/dependent measure (e.g., the effect of Ritalin on TOVA scores) or multiple variables that are considered in isolation for exploratory purposes that are not integrated under the umbrella of a driving theory or conceptual foundation. This has been demonstrated in research that was specifically designed to test the limited predictor variable premise (Carlstedt, 2001, 2004).

PRIMARY HIGHER-ORDER FACTORS: ACCOUNTING FOR MORE OF THE VARIANCE

Primary higher-order (PHO) factors that are known to have an impact on the dynamics and effects of subordinate experimental or predictor variables on specific outcome responses (dependent/criterion measures), such as hypnotic susceptibility and neuroticism, have the potential to dramatically affect the outcome of a clinical trial. However, if they are unknown or not considered, they obviously will go unnoticed despite their conceptual relevance and potential to account for significant amounts of variance that could not be explained solely on the basis of selected predictor variables in a clinical

trial. The role of PHO factors in mediating mind-body responses and their effects on clinical and performance outcome measures is often first revealed in extension studies of previous research that may have been equivocal in establishing interactional or integrative relationships between specific predictor/independent and criterion/dependent outcome. For example, in Greenberg and Kindschi's (1996) study of the effect of a psychostimulant (e.g., Ritalin) on ADD inattention symptoms, while it is possible that drug ingestion was associated with higher TOVA scores at the level of the group (statistically significant differences: pre-drug ingestion compared to post ingestion), a parallel effect size or variance-explained coefficient might be minimal. Such an outcome scenario (statistically significant between-group differences, but low effect size), while desirable and considered to be a positive outcome (statistical significance), would nevertheless contain numerous data points (study participants) that reflect minimum gains or responses that were contradictory to an investigation's hypothesis. Such findings need to be explained; we need to know why differential or no responses occur. Consequently, in an integrative extension study of a psychostimulant's effect on TOVA scores, it might be revealing to incorporate conceptually relevant PHO factors that are known to be associated with attention, the cognitive processing of affect, and physiological reactivity in order to determine to what extent, if any, psychological factors (PHO traits and behaviors) interact with a drug to mediate or statistically moderate relationships between and among the initial variables of interest in a drug trial's design (e.g., the effect of Ritalin on TOVA scores as moderated by hypnotic susceptibility and multiple pre-TOVA baseline neurochemistry/neurophysiology assessments).

PHO individual difference factors have been hypothesized to influence the manifestation of symptoms associated with numerous mental disorders, including ADD, especially as a function of specific stimuli or tasks that an individual encounters, which may not be controlled for in an investigation's design. In the context of academic performance, ADD symptoms may occur in a math class but not during an art lesson or during physical education. This could be due to the level of interest or boredom that an individual experiences when encountering a task, subject, or stimulus. PHO factors such as hypnotic susceptibility may mediate neurophysiology in ADD to the extent that a snapshot in time might reveal a more classic ADD EEG profile, or one that reflects intense engagement and attention, in both the "true" ADD and "normal" individual (Nash, 2000). For example, an individual with ADD who is low

in hypnotic susceptibility may have a greater ability to readily focus when confronted with a boring stimulus than someone who is high in hypnotic susceptibility, who would be more prone to surplus pattern recognition when encountering uninteresting stimuli and would be unable to attend. These response tendencies could be predicted on the basis of their known characteristics and as such should be considered in ADD investigations (Wickramasekera, 1988). But how likely is it that a pharmacological researcher or prescribing physician with no exposure to the literature of hypnotic susceptibility and other psychological PHO factors will integrate this and other potentially revealing measures into a clinical trial or assessment process?

Relative to the TOVA, which assesses concentration and vigilance on the basis of visual and auditory discrimination over time, without knowledge of PHO factors that can modulate attention or enhance distractibility (e.g., hypnotic susceptibility), a researcher who independently (unidimensionally) investigates the effect of a psychostimulant on changes in TOVA scores may have difficulty accounting for variability within and between participants in experimental, control, and placebo control groups. When random selection is used for subject recruitment and group assignment, potential moderator PHO variables can easily be overlooked.

The presented arguments, perspectives, and examples do not necessarily challenge the diagnostic integrity, validity, or existence of, for example, ADD and other mental disorders as legitimate mental afflictions. Nor are they meant to be an indictment of pharmaceutical trials and psychotropic intervention. However, they are intended to question whether ADD and other mental disorders can or should be viewed as pervasive brain states, replete with consistent symptoms and replicable neuropsychophysiological and neurochemical response profiles, not only at baseline but across divergent settings, situations, and ecological contexts that lead to symptoms and decrements in performance that can be universally treated pharmacologically. While the above issues and examples primarily centered on psychopharmacology and physicians who prescribe drugs as a first course of intervention, it should be noted that non-medically trained practitioners and researchers also frequently subscribe to assessment and treatment approaches that are not integrative. Analogous to psychopharmacologists not sufficiently taking individual differences into account when designing clinical trials, most psychotherapists fail to consider or are unaware of neuropsychophysiological response parameters that accompany a disorder and its symptoms and/or the PHO individual differences factors (personality traits

and behaviors) that mediate them (see Corsini & Wedding, 1995). As a result, potentially revealing mind-body markers go undocumented, leaving the diagnostic and intervention process more to chance than to an integrative evidence-based clinical strategy. For example, self-report instruments or patient feedback alone frequently lead to diagnoses of panic or other anxiety disorders; however, practitioners and patients alike know little about actual accompanying ANS correlates and the impact a selected intervention may or may not have on underlying neuropsychophysiological responses in individual patients. Yet such measures could be easily obtained by the incorporation of user-friendly monitoring devices that are capable of measuring a patient's ANS profile in the context of in-the-office stress tests and ecological, real-world settings to more objectively assess the impact of intervention.

METHODOLOGICAL ISSUES: SIGNIFICANCE TESTING AND SELECTION

While significance testing is virtually universally applied in clinical research, this statistical approach has inherent weaknesses that can lead to faulty or incomplete interpretations and premature conclusions regarding findings (Pocock, Hughes, & Lee, 1987). For one, the focus of clinical significance testing centers on selected predictor or independent variables of interest and their effect on criterion or dependent outcome measures. Although this often results in the determination that a trait, behavior, or other psychological factor is significantly more pronounced in an experimental group than in a control group or that multiple clinical predictor variables explain x amount of the variance in an outcome (criterion) measure, what is frequently not adequately considered in the significance testing or regression paradigm are individual outliers (single cases) that either did not benefit from an intervention or exhibited response parameters that differed from the majority of an investigation's participants. Since significance testing only can control for or test variables that are selected for study in the original research design, it is important to use a driving integrative conceptual model that considers as many plausible predictor or control variables that are addressed by a guiding theory (thus making it as integrative as possible). This is critical to increasing a design's experimental or exploratory sensitivity by generating and accounting for positive findings as well as determining why single-case (individual) out-

liers that exhibit responses opposite to those proposed by an investigation's hypothesis occur (Morton & Torgerson, 2003).

Although meeting or exceeding an alpha threshold results in the rejection of the null hypothesis, the fact that low to medium effect sizes, considered by many (e.g., Cohen, 1988) to be a more rigorous benchmark of therapeutic success or experimental differences, can exist concurrent to findings that support a study's hypothesis is troubling and can have major clinical implications. For example, recently, findings from a study in a long line of investigations on the placebo effect were published and promoted (Macedo, Baños, & Farré, 2008). According to a review article that the study cited, 20% of patients who were given a placebo experienced a 50% reduction in the amount of migraines that they experienced. While this is an interesting finding, what may be more important is determining why certain patients exhibited a placebo response and others did not, or vice versa. Furthermore, what are the placebo mechanisms, and did the design of these studies facilitate a better understanding of this confounding effect? Did a plausible model of mind-body functioning or conceptual foundation that could account for these and other findings on the placebo effect emerge? Is it enough to know that if one gives a placebo to migraine patients, 20% of them will get better? Or would it be better to know who is more or less likely to respond to a placebo as opposed to an active drug and why? After all, in the clinical realm, especially in private practice, it's all about the individual client or patient. While "successful" (hypothesis-consistent findings) clinical trials and research findings on interventions may highlight impressive pre- and post-study or between-group gains or differences or high amounts of variance explained, statistically significant findings can at best help guide practice, but group results mean little to an afflicted patient who is not getting better or has been misdiagnosed.

A recent example from the realm of depression research involves investigations that have attempted to disentangle complex interactions that appear to be involved in the development of cardiovascular disease (Hamer, Molloy, & Stamatakis, 2008; Whooley, 2006). If one were to rely solely on initial findings that suggest that depression itself is the primary mediating variable in the onset of acute cardiac events and only focus on the treatment of this mental disorder (depression), practitioners and patients might not achieve the result that they were expecting. That's because extant research suggests that the actual critical driving factor in the coronary artery disease equation is the lack of physical activity commonly seen in patients who are depressed, not

depression per se (Whooley, 2006). Consequently, the most effective therapy for both depression and associated coronary artery disease may be exercise based, and not the direct treatment of depression. Again, here and relative to much of the research in health psychology, psychiatry, and behavioral medicine, conclusions that lead to diagnostic and intervention decisions are being made on the basis of tenuous unifactorial designs that lead to findings that are later amended or overturned.

CONCEPTUAL MODELS AND RANDOM SELECTION VERSUS STRATIFICATION

The failure to involve or utilize integrative conceptual or guiding models of patient assessment, diagnostics, and intervention can exacerbate pitfalls that are associated with conventional approaches to the interpretation of research. For example, awareness of psychological and behavioral propensities and mind-body response tendencies can result in better participant stratification for grouping assignments in clinical research. While random selection and assignment are a requisite component of the supposed gold-standard double-blind, placebo-controlled experimental design, it is becoming apparent that stratification of participants on the basis of individual difference factors may be as important, if not more so, than random selection (Senn, 2004). In the case of the aforementioned depression–coronary artery disease studies, more aware researchers with knowledge of integrative conceptual models and relevant interdisciplinary research might have created exercise groups to test for the impact of vigorous physical activity on both depression and coronary artery disease. Much time and expense could have been spared—not to mention lives saved—had original research in this area been integrative in terms of its conceptual foundations and guiding research. Why should it take decades to arrive at a critical and potentially lifesaving finding when an integrative conceptual foundation and research model could have led to more potent and sensitive experimental designs for testing the mediating impact of exercise on depression and coronary artery disease much sooner? Instead, supposedly solid research that used significance testing as its benchmark probably led many mental health practitioners to focus on cognitive-behavioral therapy or prescribe antidepressants to alleviate depression rather than addressing the critical inactivity issue. While cognitive-behavioral therapy and/or psychotropic intervention may have resulted in therapeutic success in some cases, supposedly cured depressives who never exercise and have other

lifestyle-related risk factors may very well have gone on to develop coronary artery disease and experience eventual heart attacks. In this scenario, a lack of research integration, and practice that was not cognizant of specific psychological and behavioral factors that are associated with both depression and coronary artery disease, could have dire consequences.

This illustrates how significance testing in the context of a randomized group design may actually increase the probability that outlier patients will not be accurately evaluated or treated in the most effective manner. It also points to the fact that even patients who did experience gains following an intervention (e.g., Beck Depression Inventory score gains following cognitive-behavioral therapy or drug treatment) or exhibited more or less of a particular response or symptom (e.g., C-reactive response; Danner, Kasl, Abramson, & Vaccarino, 2003) did not necessarily do so at the same rate and thus need to be treated in an individualized manner, not on the basis of the mean benchmark values of a specific treatment group. In addition, since clinical studies are frequently time locked, and even longitudinal investigations have time limits, and almost all lack ecological validity, can we rely on temporally isolated and derived data to make critical decisions regarding patient diagnoses and treatment?

MULTIPLE SINGLE-CASE, REPEATED-MEASURES DESIGNS

While the randomized, double-blind, placebo-controlled experimental design has long been viewed as the gold-standard approach to clinical research and trials, it has major limitations in the context of clinical practice, some of which have been addressed previously (Brown & Liao, 1999; Kaptchuk, 2001). What especially stands out is that this research design arrives at group and inter-group findings on the basis of mean scores or performance metrics (averages). Although such findings can be used to guide clinical practice at the level of the individual (intraindividual), their practical clinical value may be tenuous in the context of situations, settings, and stimuli that *do not precisely replicate* the conditions of a particular investigation upon which clinical conclusions are reached and subsequent practice recommendations are made.

While the traditional gold-standard group design has an important place in clinical research, practitioner-researchers are confronted with clinical realities that limit their ability to perform individual-based intervention efficacy or outcome studies. As such, they often have no choice but to rely on group-based and con-

trolled clinical trials for guidance. However, they cannot assume that group findings will generalize to a particular patient and should view them with caution and, if possible, engage in practical and efficient intraindividual designs to better determine treatment effects.

The research design of choice at the practitioner-researcher level may be the single-case study with repeated and longitudinal measures, in which an individual serves as his or her own control. Multiple single-case studies can be aggregated into a group design, but of ultimate interest is what a single-case, repeated-measures study reveals about a single patient of interest. This design also has more clinical flexibility than classic group designs and allows for greater generalizations across settings, situations, and stimuli, since measurement occasions are repeated as needed, or on a predetermined basis, longitudinally, in the context A-B and A-B-A predictor/independent and criterion/dependent variable manipulations. It allows for the extensive investigation of intervention effects over time, which results in the generation of well-controlled data and findings on individual patient responses (Kennedy, 2004). Rather than relying on findings and recommendations that result from group clinical trials, by engaging in patient diagnosis, intervention, and outcome (efficacy) testing at the intraindividual level, a practitioner is engaging in a virtual individualized clinical trial that, depending upon design nuances, can be more revealing and of direct clinical relevance than supposed gold-standard group experimental investigations (Anderson & Kim, 2008).

An example of a multiple single-case, ecological, repeated longitudinal measures investigation is presented in a later Chapter 31. Essentially, what this performance-related study with a clinical component (individual with ADD) reveals is that despite the assumption that a particular respiratory biofeedback technique will enhance performance (on the basis of group studies), when this study design is used to analyze this technique, one observes disparate mind-body responses in heart-rate variability measures and performance outcome as a function of intervention-induced psychophysiological responding. Findings from this longitudinal study reveal that group findings, although statistically significant, did not necessarily transfer to each individual, as reflected in differential dose-response⁶ relationships as a function of individual differences (Carlstedt, 2007). This and other investigations have demonstrated that

individual response differences, or zone of optimum functioning parameters (Hanin, 1980), not only predict performance and outcome at the intraindividual level but are often inconsistent with what group studies or clinical trials have reported (mean differences). They point to the need to concurrently validate group studies through the use of (multiple) single-case, longitudinal, repeated-measures investigations lest findings based on group averages do not generalize to the individual patient, something that could have serious consequences and lead to negative clinical outcomes.

CLINICAL PRACTICE: ISSUES AND OBSERVATIONS

There is an abundance of scientific information and empirical data on physiological functioning in the context of both health and illness. When an individual goes to the doctor, he or she is usually medically tested in an attempt to arrive at a diagnosis, either preemptively (in the case of routine annual physical examinations) or to account for symptoms that the patient is experiencing. Tests of physiological functioning have been shown to achieve a high degree of diagnostic certainty, which is critical to patient well-being, treatment decisions, and predictions for patient morbidity and mortality. Rarely does one visit a physician and not leave with important test-based information about the state of one's body and health.⁷ However, the field of medicine is not infallible. Malpractice occurs, patients are misdiagnosed, and the medical paradigm is usually more reactive than proactive, with preventive medicine still being more of an afterthought than a primary interventional strategy. Moreover, there is a disturbing trend whereby physicians from specialties that are distant or ancillary to the mental health domain are treating what are primarily considered psychological disorders (Schurman, Kramer, & Mitchell, 1985). This is occurring even though many physicians admit to having insufficient training and knowledge about the psychological/mental assessment and intervention

6. Here dose-response refers to respiratory biofeedback-induced breathing parameters and changes in heart-rate variability and/or performance outcome.

7. In the context of this critique, it is necessary to distinguish the field of medicine and treatment of biologically based illness from psychiatry and other mental health specialties, including psychotherapy, that are much more "loose" or eclectic in their approaches to patient assessment and intervention. While medical research and practice are not immune from the earlier criticisms regarding methodological issues, there is a system of inquiry and accountability in place that, for the most part, does not exist in psychotherapy and many allied mental health specialties and ones that do are more perfunctory or cursory than of highest levels in the evidence hierarchy.

procedures that are actually the purview of recognized clinical specialties (e.g., clinical psychology, psychiatry, and/or behavioral medicine; Brunk, 2008). Physicians who would not think of practicing cardiology or neurology without advanced training and board certification are all too quick to diagnose and treat mental disorders (usually pharmacologically), frequently on the basis of cursory drug company–provided symptom checklists. This has led to patients with depression, ADD/HD, and anxiety disorders, among other mental health conditions, being prescribed drugs when psychological and behavioral interventions might have been as good or better at treating these and other psychological problems without the danger of side effects (Whitaker, 2007).

It is not that surprising that many physicians attempt to treat psychological disorders, since the field of medicine, and especially the pharmacological industry, has long advanced the belief that mental problems *always* have neurobiological substrates that should be treated with medication. While it is hard to dispute the idea that mental illness and psychological problems originate or are manifested centrally (in the brain) and can mediate maladaptive physiological responses and resulting symptoms, it cannot be assumed, categorically, that the best course of intervention is a psychotropic one.

Nevertheless, irrespective of these issues, the philosophical premise that drives the medical practice model is predicated on rigorous evidentiary and accountability standards. For example, when a primary care physician or internist treats a patient with depression, pharmacologically, he or she still must adhere to mandated evidence-based procedures that are in place to determine a drug's efficacy, side effects, and other neuropsychophysiological responses that are relevant to patient safety and outcome. It would be untenable to merely prescribe medication and not follow up in accord with professionally mandated procedures.⁸ While there have been major blunders on the drug front, and certainly there are physicians who have violated practice and ethical statutes regarding the administration of drugs, these things do not detract from the fact that the field of medicine has validated evidence-based practice

templates, methods, and procedures that are designed to protect patients. Essentially, the medical model eschews anecdote, and while clinical intuition plays an important role in arrival at a diagnosis, ultimately, it is the resulting test data that confirm or refute physician hunches. Thereafter, evidence-based treatment is initiated and its efficacy is tested. This systematized, evidence-based, and data-driven approach to diagnosis and intervention has resulted in large volumes of statistical information and empirical insight into disease and its etiology, along with validated treatment modalities that have been shown to ameliorate symptoms and even eradicate pathophysiology.

By contrast, the greater arena of psychotherapy and mental health services (especially in the realm of private practice) that span over 400 identified systems or approaches to patient/client assessment and intervention (Corsini & Wedding, 1995) is to a large extent an anecdote-based domain in which practitioner impressions and intuition rule (Nathan, 2004). With the exception of neuropsychology and certain intervention procedures that are used in clinical/health psychology and behavioral medicine, there are few forms of accountability and documentation that would qualify as being of the highest level in the evidence hierarchy (Patel, Butler, & Wells, 2006). Session notes do not necessarily count as having high evidentiary value, since they usually merely bring to paper subjective ideas, impressions, patient feedback, analyses, and/or diagnoses that fit the particular theoretical-practice orientation or school of thought of that a practitioner subscribes to.

Moreover, patients often find themselves thrust into a particular system of psychotherapy or treatment by chance, irrespective of their symptoms, which leads them to be treated randomly by practitioners who may have no experience dealing with or even recognizing a particular disorder. For example, a patient with depression or an anxiety disorder who arbitrarily selects a psychotherapist from the phone book—say, a psychodynamic-oriented practitioner—may spend weeks exploring and discussing his or her life history and upbringing. While such free association or guided analysis may show the patient that the therapist is competent and engaging in a viable treatment approach, both parties may be oblivious to the potential medical risks and consequences of differential states of ANS activation that underlie symptom manifestations of depression and anxiety and that need to be addressed immediately, either behaviorally or pharmacologically. Ideally, a patient who has depression or anxiety would be referred to a specialist to assess ANS activity so that an outcome

8. Although this example may appear to contradict the previous critique that was leveled at physicians who diagnose and treat mental disorders but are not adequately trained, once a course of intervention is initiated, practice dictates must be adhered to in the interest of patient health. Consequently, while a physician may not know enough about the psychological and mind-body etiology of a mental disorder (from the perspective of, for example, a clinical psychologist), he or she must still apply treatment modalities with extreme care and oversight to ensure patient safety.

can be predicted and the proper primary or adjunct approaches to treating what are essentially neuropsychophysiological disorders can be determined. However, this rarely occurs in the realm of private practice, where patients are at a premium and most mental disorders that are encountered by clinicians are automatically considered to be within their purview, irrespective of the type of training they have received. Essentially, in the mental health arena virtually all schools of thought readily adapt their interventions to accommodate the treatment of just about any disorder in accord with a system of psychotherapy's established procedures, even if doing so could be considered clinically and empirically tenuous. Since most psychotherapists and systems of psychotherapy have in place methods and procedures that were designed to treat numerous common mental disorders within the context of their own in-house research and guiding theoretical models, it is doubtful that proponent practitioners routinely look beyond their domain for intervention support or make referrals even when these are clearly indicated.

However, they often should, since subliminal maladaptive mind-body responses can be insidious, and while they may be (or are assumed to be) attenuated during therapy of any kind (self-disclosure is associated with autonomic nervous system balance; Pennebaker, 2000) over time, they can, if not aggressively treated, lead to a host of symptoms and illnesses (e.g., coronary artery disease, suppressed immune response). In other words, even when a therapy session may seem relaxing to a patient (and the therapist may infer such), a temporary reduction in sympathetic nervous system activation once a week for an hour may be insufficient to ameliorate or eradicate the chronic hyperreactivity that frequently exists in depression and anxiety patients. This highlights the need to incorporate integrative methods and procedures that transcend the focal philosophical/therapeutic orientations of a specialty practitioner into all psychotherapy and mental health practice to better serve the interests of patients who may not know whom to seek for help with complex problems that may extend well beyond a specific symptom, diagnostic label, and approaches to treatment that are endemic to a particular system of psychotherapy that may be insufficient.

Many mental health care practitioners (of diverse and even diametrically opposed persuasions) may vehemently disagree with the above critique and examples and counter that there are numerous empirically validated interventions that they can opt to use to treat any number of conditions. Psychoanalysts might claim that have successfully treated patients with depression

and anxiety through insight- and awareness-oriented procedures and analysis, maintaining that clinical impressions and patient feedback are the only evidence needed to demonstrate positive therapeutic outcomes. Some practitioners may further argue that the level of accountability and evidentiary standards that are required in medicine are unrealistic, impractical, and superfluous when it comes to psychotherapy. They may also contend that psychopathology is too complex to localize anatomically and functionally and wonder what impact such knowledge would have on the actual remediation of symptoms even if one could accurately link abnormal behavior with specific parameters of brain functioning. In other words, do we need to know what is happening at the cellular level to understand mental illness and the effects of treatment? Ultimately, isn't it about what the patient feels or reports and how he or she behaves and performs in the real world that determines the efficacy of an intervention (Hoffmann & Weinberger, 2007)?

Others may argue that psychotherapy is as much an art as it is a science, and therefore medical diagnostic procedures and evidentiary standards cannot be demanded of a process whose goal it is not necessarily to "cure" patients but to offer them help, support, and skills that will enable them to better deal with their problems. This process is not necessarily quantifiable, and certainly the control aspects of empirically documenting an intervention ecologically and longitudinally are, at best, extremely limited (Hoffmann & Weinberger, 2007).

While these arguments may have some merit, one cannot ignore the fact that cognition and behavior have biological and physiological consequences, as do aberrant or dysfunctional thinking and responding. Similarly, therapeutic attempts to mitigate the effects of psychopathology or enhance mental functioning and performance as well as address personal, relational, and family issues are associated with individual neuropsychophysiological responses. These need be assessed and documented, irrespective of a practitioner's system of psychotherapy or practice orientation and the supposed limitations that are thought to compromise attempts to do so. From an integrative, evidence-based perspective, one cannot ignore the fact that every patient and associated psychological, behavioral, or psychiatric problem has a mind-body signature that can predict and affect morbidity and even mortality. As such, practitioners should be cognizant of mind-body response tendencies that are manifested concomitant to symptoms that occur in any number of mental disorders. Practitioners also need to be aware of conceptual

underpinnings and mediating mechanisms that signal that something is amiss and transcend verbal report or clinical intuition (which can be misleading or inaccurate). These mechanisms can also be assessed, monitored, and analyzed for comparative purposes in the context of pre-intervention diagnostics/assessment and intervention-induced changes (or lack thereof) and for determining overall intervention efficacy at the intraindividual level.

CLINICAL PRACTICES IN MENTAL HEALTH: WEAKNESSES AND OVERSIGHTS

Although highly variable in terms of quality or evidentiary status, current practice approaches in clinical psychology, psychiatry, and behavioral medicine tend to exhibit a number of common weaknesses or shortcomings. They have resulted in part from a failure to validate many of the theories, assumptions, and myths that drive prevalent approaches to clinical practice, and untenable and unsupported approaches continue to persist as though they were valid. Prevalent practice approaches are marked more by what they don't include and involve than what they do.

Intake Sessions Are Often cursory

Practitioners rely to a large extent on patient input or answers to questions about psychological issues and problems or context-inappropriate test instruments to arrive at a diagnosis or insight regarding patient functioning. While the establishment of rapport through patient-therapist communication is important, subliminal mind-body response tendencies that often transcend conscious awareness are usually not assessed. Such mind-body processes are frequently overlooked despite their ability to help predict patient/client responding, explain the etiology of psychological issues/symptoms, and determine intervention amenability and compliance and probability of intervention success. Most intake sessions usually do not incorporate key individuals in a patient/client's life in order to obtain corroborating feedback, and plans are rarely laid for later ecological evaluations and longitudinal follow-up and analysis.

Practitioners Rarely Leave the Office

The vast majority of practitioners do not engage in out-of-the-office observations and evaluations, and many never leave their practice to actually observe a patient/

client in real-world settings that may be of clinical relevance. Consequently, major discrepancies between patient in-office self-report and actual responses to real-life situational stressors may go unnoticed. Incongruence between patient feedback, practitioner impressions, and actual underlying patient neuropsychophysiology and its effect on objective outcome measures (obtained in the field) frequently render in-office diagnostic conclusions incomplete, inaccurate, and/or flawed and prevent practitioners from determining the extent to which an intervention is being used by a patient, if at all, and whether it is generating a desired mind-body response. For example, it cannot be assumed that because a practitioner is convinced that a patient has learned a cognitive-behavioral therapy technique (e.g., thought stoppage) in the office, he or she is capable of using this method to stop a panic attack and induce a return of a homeostatic autonomic nervous system baseline state in the real world.

Practitioners Rarely Make Referrals

Practitioners, regardless of limitations in education, training, and expertise in a specific clinical area, tend to take on every case. Most seem very confident that they can handle any clinical issue. What is troubling is that very few practitioners are aware of what they don't know, especially regarding neuropsychophysiological dynamics that are associated with specific psychological conditions or disorders or should occur in the context of certain interventions that are designed to reduce symptoms or improve performance and cognition through the manipulation of mind-body systems. As previously mentioned, practitioners tend to intervene in accord with how they were trained and often do not know what they don't know. This can affect patients negatively, especially since mental disorders have health consequences.

Practice Approaches Are Eclectic and Rarely Documented, Validated, or Tested for Efficacy

Select ten practitioners at random, and one is likely to find ten different approaches to the evaluation of patients and subsequent selection and application of interventions. The lack of a systematic evidence-based approach to assessment and treatment can prevent patients from obtaining a valid diagnosis and reliable information regarding symptoms and psychological responses to real-world stressors and attempts to manipulate mind-body responses through an intervention.

Unfortunately, many practitioners are not aware that something may be missing from their practice repertoire, training/education, and knowledge base or are reluctant to admit to such (this is particularly the case among highly credentialed or experienced, “star,” or supposedly stalwart practitioners who tend to remain married to the systems that led to their notoriety). Yet many practitioners and systems of psychotherapy tout and promote their methods with utmost confidence to the extent of guaranteeing the validity and efficacy of their methods or approaches to clinical diagnostics and intervention. The eclectic practitioner-centered basis of mental health practice would be untenable in the medical arena, where procedural competence and data-driven accountability are demanded and one’s scope of practice is limited to specialty domains, a concept that is essentially foreign to the broad clinical arena of psychotherapy, where an “everything goes” attitude pervades.

Practitioners Fail to Utilize Advanced Technologies and Methodologies

Most practitioners lack training in applied psychophysiology, applied neuroscience, ambulatory monitoring, and the use of psychophysiological instrumentation/software, procedures, and methodologies for real-time ecological in-vivo monitoring and analysis of patients. They also lack training in biofeedback and knowledge pertaining to its utility as an out-of-office intervention that can be used to manipulate or shape desired psychological or mind-body responses (attention, physiological reactivity, and cognitive processing) and then determine the extent to which such attempts were successful. These advanced technological procedures allow for the documentation of patient responses, bringing accountability to the assessment and intervention process in the context of ecologically valid settings and situations, namely, patient functioning in the real world.

Practitioners Fail to Engage in Intervention Efficacy and Outcome Studies

Most practitioners also fail to employ single-case longitudinal statistical analysis strategies to generate response-specific databases in follow-up to or in conjunction with every psychotherapy intervention or real-world monitoring session. The application of methods and statistics that are tailored for determining individual response tendencies across conditions (e.g., baseline vs.

stressor condition) and the efficacy of an intervention (pre- vs. post-intervention testing) are crucial for attaining high-level evidentiary procedural and predictive validity and should be used by all serious, conscientious, and ethical practitioners or outsourced to specialists who are trained in such methods and procedures.

Interventions Are Applied in a Haphazard, Ad Hoc Manner

Patients are often taught visualization/relaxation techniques, cognitive strategies, breathing techniques, and other methods in the context of the intake or initial psychotherapy sessions and then sent on their way under the assumption that (1) they have learned an intervention technique and are capable of engaging in it at will, (2) that the temporal properties of an intervention technique are such that they can be applied at any time and then work later or on command, and (3) that learned intervention responses that were shaped in the office will generalize to the real world. While most clinical intervention techniques are designed to relax a patient, very few practitioners actually monitor them under real-world conditions or in context-specific situations or settings that elicit maladaptive neuropsychophysiological responses for the purpose of determining (1) whether a patient is/was engaging in the prescribed intervention, (2) whether neuropsychophysiological responses are/were associated with an intervention outside of and in actual isolated settings and situations that were predetermined to elicit maladaptive mind-body responses (and if so, what sort), and (3) whether engaging in an intervention really ameliorated symptoms or enhanced cognitive/mental control and performance and, if so, to what extent the assumption of intervention efficacy can/could be validated (on the basis of objective statistical outcome measures that are accrued longitudinally at the intraindividual level).

The field of psychotherapy remains mired in a practice paradigm that is based in part on weak data, questionable assessment methods, and interventions that have not been validated. The above examples are just a few of numerous practice oversights and weaknesses that preclude practitioners from engaging in high level evidence-based best practices. If the field of psychotherapy is to provide patients and clients with best practices, fundamental changes in the way they are assessed and treated need to be made. Integrative, standardized, and validated approaches to the evaluation of patients must produce meaningful and useful information regarding psychological responses and behavior that has a high degree of ecological and predictive validity and reliability.

Practitioners need to be provided with evidence-based assessment and intervention methods that generate measures and parameters of clinically relevant psychological and neuropsychophysiological functioning for the purpose of arriving at accurate diagnoses, predicting response tendencies across situations and settings, guiding the selection of appropriate interventions so as to enhance treatment amenability and compliance, and determining their efficacy. The time has come for clinical psychologists, psychiatrists, behavioral medicine specialists, and other allied mental health practitioners to engage in a new practice paradigm.

RECOMMENDATIONS: INTEGRATIVE CLINICAL RESEARCH AND PRACTICE

The disintegrated state of clinical research and practice can in part be attributed to the fact that education and training have become more specialized and compartmentalized and are commonly carried out in relative isolation, with domain-specific findings, methods, and procedures not being adequately disseminated or shared across disciplines and professions (e.g., medicine and psychotherapy). Teams of specialists, specialty laboratories, and training programs that narrowly focus on specific methodologies, singular measures, and niche lines of research and practice pervade and are further constrained by theoretical and technological limitations that remain unknown across disciplines.⁹ Findings and relevant conceptual models that may help explain certain clinical phenomena and lead to improved integrative diagnostics and interventions frequently languish within the domain or specialty area of their origin.

Relative to clinical practice, clinicians' psychotherapeutic orientations usually develop as a result of their exposure to a training program and allied faculty's school of thought or specialty, interests, and/or ongoing lines of research. After being trained to administer a particular clinical assessment and intervention protocol, students tend to practice what they were trained to do for their entire career. This dynamic does not necessarily foster integrative clinical practice. Instead, practitioners continue to focus on measures and procedures within the scope of their training and expertise, dispens-

ing theory-based advice and performing specialty interventions with a high level of confidence that they are adequately evaluating and treating patients that may be unjustified.

The following recommendations should be considered by researchers and practitioners who are interested in advancing integrative clinical research and practice:

- (1) Medical and pharmaceutical researchers should incorporate psychological researchers and other specialists (e.g., psychophysiolologist or neuroscientist) into their investigations as consultants. It is important for physician-researchers and pharmacologists to be aware of psychological factors, especially PHO individual difference measures, that can affect basic biological and pharmacological research. It should not be assumed, however, that all psychologists are aware of crucial PHO factors that are conceptually relevant to the development of psychotropic medication; as such, caution should be exercised when one seeks non-medical consultants.
- (2) More is better in terms of predictor and criterion variables. Rather than strictly focus on, for example, the effect of Ritalin on attention or ADD symptoms, it is advisable to investigate medications in the context of extensive personality, behavioral, and neurocognitive measures that are conceptually relevant to or have been associated with mind-body dynamics that are hypothesized or known to underlie a disorder's symptoms or the effects of a drug (for example, controlling for neuroticism and ANS activity in the context of participant selection for an ADD study). Sensitive micro-level outcome measures might include variable baseline conditions in which ADD is assessed for participant selection, multiple performance tests, and indices that are structured to take level of interest or boredom into account. Ecological measures such as performance during sports or challenge activities should also be integrated into ADD and other clinical and drug investigations both in the context of intervention and non-intervention phases and, preferably, longitudinally.
- (3) Neuropsychophysiological assessment, including qEEG and heart-rate variability measures, should be incorporated into all psychological, psychiatric, and pharmacological studies and clinical trials in the context of baseline readings, laboratory-based stress tests (e.g., the serial 7s test), performance outcomes (lab based and performance paradigm or outcome measure specific), and longitudinal eco-

9. For example, few psychiatrists and psychologists are aware of or use soft- and hardware that can entrain thorough biofeedback cardiovascular responses that can immediately arrest panic-attack symptoms or induce vasodilation to lower blood pressure.

logical outcome measures (e.g., grade point average, drug dosage) and as a function of select PHO psychological factors.

- (4) Integrative interdisciplinary databases and repositories of study designs and methodology need to be created, articles need to be published, and other relevant information needs to be developed in order to advance better information sharing and communication among specialties. An integrative institution or professional society should coordinate investigations and grant submissions as well as promote the advancement of integrative education and training programs within medical schools, professional psychology schools, and schools in allied mental health disciplines.
- (5) As the most disparate and eclectic body within the mental health domain, private practitioners should be trained to integrate user-friendly methods and procedures into their intake, assessment, and intervention processes, irrespective of their school of thought or practice orientation, which will afford them the opportunity to contribute to a universal database on patient/client mind-body functioning for, initially, descriptive and exploratory and, later, experimental purposes. Such a universal clinical trial will lead to the generation of vast amounts of integrative information on patient/client functioning during intake and assessment and pre- and post-intervention phases of psychotherapy—information that can benefit practitioners, researchers, and patients and contribute to the advancement of integrative clinical science and practice.

Chapter 31 presents an integrative, multi-modal, and interdisciplinary protocol. It is based on a promising multifactorial, multidimensional, and conceptually oriented mind-body model that takes the above critique and recommendations into account and has been field tested over the last 10 years.

Critical Thinking and Evidence-Informed Practice as Guides to Clinical Decision Making

Eileen Gambrill

Professionals are required to be familiar with and honor professional codes of ethics. Examples of obligations described in such codes include the obligation to draw on practice and policy-related research, accurately inform clients of the risks and benefits of recommended procedures and alternatives, treat clients with respect, and act with integrity. Research regarding the extent to which helpers honor such obligations shows that the rhetoric in such codes does not match reality. For example, many helpers do not honor requirements for informed consent (e.g., Braddock, Edwards, Hasenberg, Laidley, & Levinson, 1999). Professional practice today includes services based on the latest research, in which clients are involved as informed participants, as well as the continued use of services that have been carefully evaluated and found to be harmful. Most services are of unknown effectiveness. Books such as *Science and Pseudoscience in Clinical Psychology* (Lilienfeld, Lynn, & Lohr, 2003) and *Controversial Therapies for Developmental Disabilities: Fad, Fashion, and Science in Professional Practice* (Jacobson, Foxx, & Mulick, 2005) remind us that the follies and fallacies that occur in the area of health care (e.g., Skrabanek & McCormick, 1998) also occur in our field. Failure to keep up with

practice-related research findings makes it impossible to honor informed-consent obligations and may result in decisions that harm rather than help clients.

The term *integrative* in the title of this book draws attention to the need to look broadly as well as critically at literature in a variety of fields as this may inform efforts to help clients and avoid harm, including research regarding propaganda and its effects, for example, hiding harms of recommended practices. Integrating diverse views requires a readiness, even an eagerness, to recognize when others have better ideas and sounder evidence. It requires us to broaden our research efforts to include methods that allow for a contextual understanding of troubled and troubling behavior. Obstacles to an integrative perspective in which we critically examine the potential contributions of a variety of areas are many. They include the “siloh” mentality, in which we read only in our own area, ignoring other perspectives and related evidence, and reluctance to recognize that our views are incorrect—that we may not have the inside scoop on the truth. The history of science and medicine shows this reluctance (Popper, 1994). Yet another obstacle is the failure of professional education programs to lay down skills in critically appraising

research related to practices and policies. Concerns have been so great in psychology that McFall (1991) has called for the creation of a new accrediting body.

A siloh mentality fosters a reluctance to search broadly for material that may help us help clients and avoid harm and a reluctance to critically appraise what we find as well as what we do, and to what effect. This approach has resulted in avoidable harms to clients, including the continued use of harmful interventions such as “scared straight” programs designed to decrease delinquency (Petrosino, Turpin-Petrosino, & Buehler, 2003), brief psychological debriefing (Rose, Bisson, Churchill, & Wesseley, 2002), and brushing (Kay & Vyse, 2005) to name but three of scores of examples. Harmful interventions include bogus assessment and diagnostic systems that lead us astray in making recommendations (Jacobson, Foxx, & Mulick, 2005; Lilienfeld, Lynn, & Lohr, 2003). Consider the use of the reflex anal dilatation test, which resulted in scores of children being removed from their homes on the grounds that they were being sexually abused when they were not (Collins, Kendall, & Michael, 2001; Hobbs & Wynne, 1989). Consider also the repressed memory wars (Loftus & Ketchum, 1994; Ofshe & Watters, 1994). Hundreds of ineffective assessment and intervention methods continue to be used. Does this help clients? This siloh mentality encourages self-propaganda in which we do not critically appraise practice and policy claims as well as susceptibility to propaganda promoted by others involved in the helping professions. Harms of propaganda include removing valuable opportunities, hospitalizing people against their will, stigmatizing by means of negative diagnostic labels (e.g., Caplan & Cosgrove, 2004), and not fully informing clients, with the result that they make decisions they otherwise would not make (Scull, 2005; Sharpe & Faden, 1998; Valenstein, 1986).

PROPAGANDA IN THE HELPING PROFESSIONS

Propaganda refers to encouraging beliefs and actions with the least thought possible (Ellul, 1965). This is accomplished in part by hiding information that we would consider in making decisions if we were aware of it. Ellul (1965) argued that because propaganda is deceptive, it always has a negative effect. Isn't one person's propaganda another person's carefully gathered evidence? Using the definitions of propaganda and critical inquiry presented here, it is not. For example, in the former, evidence against favored views is hidden. In critical appraisal, evidence related to claims is actively sought, such as critical tests, and open discussion of competing

views is valued (Popper, 1972, 1994). Propaganda ploys are used to influence the choices we make while giving us the illusion that we freely make these choices. Common propaganda ploys in the helping professions and related industries such as big pharma include the following:

- Hiding limitations of research
- Preparing uncritical, incomplete research reviews related to a practice or policy (e.g., omitting research with negative findings)
- Ignoring counterevidence to favored views
- Creating bogus risks and problems
- Ignoring or misrepresenting well-argued alternative views and related evidence
- Arguing *ad hominem* (attacking the critic) rather than *ad rem* (responding to the argument)

Indications that propaganda is alive and well in the helping professions include the following:

- Children have been killed as a result of methods such as “rebirthing,” and blinded by use of oxygen at birth (Silverman, 1980). Some scholars suggest that the history of psychiatry is one of harming in the name of helping (e.g., Valenstein, 1986). Relatively little attention has been paid to adverse events in psychology and social work. (For notable exceptions see Jacobson et al., 2005.)
- Programs that have been critically tested and found to be harmful are widely used. For example, “scared straight” programs designed to decrease delinquency have been shown to increase it (Petrosino, Turpin-Petrosino, & Beuhler, 2003) but are still used.
- Most assessment and intervention methods used are of unknown effectiveness in relation to hoped-for outcomes; they have not been critically tested to determine if they do more good than harm.
- Programs that have been critically tested and found to be helpful are not widely used (see, e.g., Evans, Thornton, & Chalmers, 2006).
- Controversies regarding the evidentiary status of practices and policy are often hidden. Consider Littell's (2005, 2006) critical appraisal of multisystemic family therapy. (See also Henggeler, Schoenwald, Borduin, & Swenson, 2006.)
- Inflated claims of effectiveness abound; they misrepresent (inflate) the evidentiary status of methods, often by hiding limitations of research, such as lack of a comparison group (e.g., Rubin & Parrish, 2007). Corporate interests in maximizing profits, for example, on the part of pharmaceutical companies encourage bogus claims in the pursuit of profits (e.g., Brody, 2007; Kassirer, 2005). If professionals are so effective

in resolving or preventing problems, as claimed by book titles such as *A Guide to Treatments That Work* (Nathan & Gorman, 2007), and *What Works in Child Welfare* (Kluger, Alexander, & Curtis, 2001), why do problems remain so prevalent?

- Screening programs are promoted even though there is no evidence that they do more good than harm. These often are subsidized by professional organizations and pharmaceutical companies with special interests.
- Claims of knowledge regarding the causes of troubled and troubling behaviors such as attributing delusions or hallucinations to schizophrenia or claiming that behaviors associated with ADHD (Attention Deficit Hyperactivity Disorder) are the result of a “brain disease” are often grossly inflated, creating an illusion of knowledge (e.g., see Boyle, 2002; Leo & Cohen, 2003).

Interrelated kinds of propaganda in the helping professions include deep propaganda, which obscures political, economic, and social contingencies that influence problems such as alcohol abuse, anxiety, and depression and the questionable accuracy of related assumptions about their causes, for example, labeling hundreds of behaviors as mental disorders requiring the help of experts (e.g., see Houts, 2002; Szasz, 1987). It includes inflated claims of effectiveness regarding practices and policies that woo clients to professionals and professionals to professions (e.g., see Rubin & Parrish, 2007). Consider the following examples.

Significance Turkey	Lauds significant results even if they are not clinically significant. Even if a finding is statistically significant, is it large enough to make any real difference to clients?
Nerd of Nonsignificance	Assumes there is no real relationship between two or more variables because none was found in a study.
Test Bloater	A person who has unwavering (and unwarranted) enthusiasm for predictive utility of a new test.
Diagnostic Zealot	Overzealous peddler of the latest diagnostic test. He has fooled himself (and may fool you too) into untested belief in the benefits of a diagnostic test.

Bogus claims include those regarding the accuracy of theories, effectiveness of intervention methods, accuracy of diagnostic methods, alleged risks, and potential consequences of public health interventions such as screening all residents of a community for mental health problems. Thornley and Adams (1987) reviewed data in 2,000 trials on the Cochrane Schizophrenia Group’s register and found consistently poor quality of reporting, which they suggest “is likely to have resulted in an overly optimistic estimation of the effects of treatment” (p. 1181). Less rigorous studies report more positive findings compared to research that controls for biases. Consider the history of facilitated communication. This intervention method is designed to increase verbal communication of people with disabilities. Initial anecdotal and pre-post reports suggested that this was effective. Later, more rigorous studies found no effect (Jacobson, Mulick, & Schwartz, 1995). Behind many recommended interventions lies a belief about how behavior can be changed that is not compatible with empirical data (e.g., see Moncrieff, 2008).

Common propaganda methods include appeals to emotion rather than reason; suppression of important information, such as alternatives to a preferred practices; distortion of disliked perspectives; use of glittering generalizations (e.g., proven); and diversion from the critical examination of claims (for example, by making jokes). These methods may be used to hide the lack of match between problems and remedies promoted and related evidence, for example, by directing attention away from environmental causes of poor health, such as psychological stress resulting from low social ranking and chronic deprivation (Gilbert, 1989; Lewontin & Levin, 2007) as well as to hide harming in the name of helping. They are used to hide evidence gaps (gaps between what is claimed and what has been found via critical inquiry). The effects of propaganda depend in part on the balance of knowledge and ignorance concerning how to achieve an outcome, such as decreasing depression or increasing social support. The effects also depend on literacy and critical appraisal skill of readers and viewers. For example, in his editorial “Time to Ban Direct-to-Consumer Prescription Drug Marketing,” Stange (2007) argued that one unintended consequence of direct-to-consumer advertising is increasing inequalities in health care and health because limited literacy and health knowledge decreases comprehension of ads.

Rather than recognizing counterarguments to preferred views, these are often hidden by the common propaganda method of censorship. For example, in the book *Assessment and Treatment of Childhood Problems* by Schroeder and Gordon (2002), there is no mention of critiques of the psychiatric classification system

(e.g., see Kutchins & Kirk, 1997). Cultural critiques of the label ADHD are not cited (e.g., Diller, 2006; Timini, 2002). Increasing attention is being given to the prevalence of bogus claims in the helping professions. Such claims may harm (and have harmed) clients in the name of helping them. Professionals whom clients trust to guard their interests are often influenced by biased material prepared by public relations firms hired by pharmaceutical companies (Brody, 2007). Consider the promotion of social anxiety as a mental disorder by a public relations firm hired by a drug company (Moynihan & Cassels, 2005). The very creation of “mental disorders” included in the *DSM* is influenced by drug companies as illustrated by ties to the pharmaceutical companies on the part of consensus task-force group members. For example, 100% of those who served on task forces on mood disorders and schizophrenia had ties to Big Pharma (Cosgrove, Krinsky, Vijayaraghaven, & Schneider, 2006). Over 50% of members of other task forces have such ties.

Content analysis of direct-to-consumer ads of drugs, introduced in 1997, showed these to be highly biased and replete with emotional appeals. “Despite claims that ads serve an educational purpose, they provide limited information about the causes of a disease or who may be at risk; they show characters that have lost control over their social, emotional, or physical lives without the education; and they minimize the value of health promotion through lifestyle changes. The ads have limited educational value and may oversell the benefits of drugs in ways that might conflict with promoting population health” (Frosch, Krueger, Hornik, Chronholm, & Barg, 2007, p. 6). Stange (2007) views the harmful effects of direct-to-consumer ads as an emerging health tragedy. Distinctions among services with different degrees of effectiveness are obscured by propaganda in the helping professions such as inflated claims of “what is known” and inflated claims regarding risks and prevalence (see, e.g., Best, 2004). Many efforts described as scientific research or scholarly inquiry do not reflect the values, aims, or methods of science such as self-correction and transparency concerning what is done, and to what effect (e.g., Evans, Thornton, & Chalmers, 2006). Ionnides (2005) argues that most research findings in biomedical research are false. Even a cursory examination of content on the Internet, in newspapers, and in the professional literature indicates that there is a continuing need to remind ourselves of the pervasiveness of bogus claims of knowledge and its effects. Inadequate education about what science is and what it is not; lapses in scholarship on the part of academics and researchers; and the daily barrage of propaganda in

the media, often in the guise of scientific research, blur the distinction between science and pseudoscience, often with harmful consequences for clients. We live in a sea of propaganda pitches, including propaganda in the helping professions and related industries. These include inflated claims of knowledge (“what we know”) about causes, the effectiveness of proposed remedies, the accuracy of assessment methods, and the prevalence of problems and risks. There is advocacy in place of evidence.

Much content in professional sources is so vague that we must wonder what purpose it serves other than to give an illusion that we are being informed. For example what do vague terms mean such as “more likely,” “associated with,” “less likely”? Such terms have very different meanings (Timmermans, 1999). Do the references attached to claims contain supportive evidence? Troubling gaps between obligations of researchers to report limitations of research, prepare systematic reviews, and accurately describe well-argued alternative views and what we find in published literature were key reasons related to the development of evidence-informed practice and policy. International conferences are now held to discuss the problems of peer review and to develop strategies to make this a fairer, more accurate process. Poor-quality research continues to appear in professionals journals (Altman, 2002). There are many reasons for this including the special interests of those who fund research such as pharmaceutical companies (e.g., Angell, 2004; Bodenheimer, 2000; Brody, 2007). We often find little match between questions addressed and use of methods that can critically test them together with hiding limitations and inflated claims of effectiveness. In place of critical, systematic reviews of research, we find fragmented, uncritical reviews (Oxman & Guyatt, 1993). Most reviews do not tell us how they searched, where they searched, and what criteria they used to review studies and do not search for unpublished as well as published reports. Conclusions drawn based on unsystematic reviews are often quite misleading. As Rosenthal (1994) suggests in his description by hyperclaiming (telling others that proposed research is likely to achieve goals that it will not) and causism (implying a causal relationship when none has been established), “Bad science makes for bad ethics” (p. 128). Chalmers (1990) argues that failure to accurately describe research methods used is a form of scientific misconduct.

Propaganda in the helping professions creates and maintains the belief that professionals are in possession of unique knowledge that can benefit those they claim to serve. In some cases this is true. In others it is not.

Critics of the helping professions call our attention to mismatches between what is claimed via certification and professional licenses and what is offered to clients. Dawes (1994) has argued that research shows that those without certain credentials, licenses, and experience are often as effective in achieving a range of outcomes as those who have them.

Critical appraisals of practice-related literature in clinical psychology and psychiatry illustrate the prevalence of pseudoscience (e.g., Boyle, 2002; Lilienfeld, Lynn, & Lohr, 2003), material with the trappings of science without the substance (Bunge, 1984). What is popular as an alleged cure changes with relatively little regard for what actually helps clients. False claims of effectiveness and false claims regarding causes result in a variety of avoidable negative consequences: clients (1) fail to gain help that is available and is desired, (2) are forced to accept “help” they do not want, (3) are offered and accept help that is not needed, and (4) use services that lessen rather than enhance quality of life; that is, interventions that result in iatrogenic (harmful) effects. A key purpose of propaganda in the helping professions is to hide these avoidable negative consequences. Professionals are typically not well educated concerning harms that may affect clients who are so unfortunate to experience them. Psychological needs such as security, belonging, and hope for relief from distress are met by seductive offers by professionals with a profit or “prophet” motive, illustrating the symbiotic interactions between buyers and sellers of propaganda. Consider the National Alliance for the Mentally Ill (NAMI) and Children and Adults with Attention Deficit/Hyperactivity Disorder (CHADD), which are comprised mostly of people struggling with the troubling behaviors of their relatives. Pharmaceutical companies eagerly fund such “consumer” organizations as a way to promote their products and the grand narrative of a biomedical solution for life’s troubles.

Professional organizations that need money and want to expand the turf of their membership accept money from pharmaceutical companies to fund continuing education programs and conferences, including specialized symposiums. Indeed pharmaceutical companies fund most continuing education in psychiatry (Brody, 2007). This troubling connection has come under increased scrutiny. Such interrelationships and related conflicts of interest forward certain views of life and solutions for problems, indeed often defining what our problems are in accord with products promoted to address “alleged” problems. Consider Prozac. Promotion of this medication rests on a given view of life and remedies (Elliott & Chambers, 2004). As a result

of a Hastings Center Report that raised concerns about Prozac, the Eli Lilly Corporation, the Hastings Center’s largest corporate donor, withdrew its financial support (Elliott & Chambers, 2004, p. 11). (See also Elliott and Chambers’s discussion of the withdrawal of a job offer by the University of Toronto to David Healy as a result of his paper “Good Science or Good Business?” in which he raised concerns about harmful effects of a drug produced by a drug company which provided funding to this university.) Different views of our troubles are related to different beliefs about behavior and the “Human Condition” (Arendt, 1958). The human condition is not an easy one, as illustrated by literature throughout the centuries as well as reports of social scientists. Is a drug the most effective way to address life’s problems, including alienation and existential moral conflicts? Many argue that dubbing all forms of depression and anxiety mental illnesses reflects a narrow distorted view of our human condition (e.g., Horowitz & Wakefield, 2007; Szasz, 1994). And what happens when the anxious or depressed stop taking Prozac? Have they solved their problems? No doubt some are helped by such drugs. But what about others?

Benefits of propaganda in the helping profession include offering hope, saving time needed to carefully consider decisions, getting rid of troubling people, escaping responsibility for unethical and avoidable harms to others because one has a “mental illness,” and muting the impact of inevitable changes and difficulties of life. Ellul (1965) masterfully portrayed the intimate connection between psychological needs and propaganda. But in the process, options to struggle with life’s conflicts and moral dilemmas and perhaps alter disliked circumstances are surrendered (see, e.g., Elliott [2004] *Pursued by Happiness and Beaten Senseless: Prozac and the American Dream*). As always, we should consider both short- as well as long-term consequences. For example, a client may feel less anxious when taking Prozac and find it easy to socialize, but what about when he stops?

THE INTEGRAL ROLE OF CRITICAL THINKING VALUES, SKILLS, AND KNOWLEDGE IN AVOIDING PROPAGANDA AND MAKING SOUND DECISIONS

Critical thinking involves the careful appraisal of beliefs and actions to arrive at well-reasoned ones that maximize the likelihood of helping clients and avoiding harm.

It involves reasonable and reflective thinking focused on deciding what to believe or do (Ennis, 1987). Critical thinking knowledge, skills, and values can help professionals to critically appraise claims and arguments, use language clearly, recognize affective influences on decisions, avoid cognitive biases that interfere with sound decision making, and spot pseudoscience and quackery and minimize their influence. Critical thinking skills are of value in avoiding reliance on questionable grounds for accepting claims about what may be true or false, such as authority, popularity, or tradition (Gambrill & Gibbs, 2009). Viewed broadly, the process is part of problem solving—for example, providing strategies to check intuitive assumptions (Hogarth, 2001). Critical thinking skills involve more than the mere possession of knowledge and skills; it requires using them in everyday situations and acting on the results (Paul, 1993; Paul & Elder, 2004). It requires clarity of expression, critical appraisal of evidence and reasons, and consideration of well-argued alternative points of view. Critical thinkers question what others take for granted. They ask questions such as: Could I be wrong? Have there been any critical tests of this claim? If so, what are the results? How representative were the samples used? Were studies relatively free of bias? Are the facts presented correct? Has counterevidence been presented? Are weak appeals used, such as to emotion or to special interests? The importance of thinking critically about claims of knowledge and the strategies used to forward them is highlighted by the history of harming in the name of helping in the “helping” professions.

Critical thinking involves the accurate presentation of well-argued alternative perspectives and attention to the process of reasoning, not just the product. Critical thinking and scientific reasoning are closely related. Both value clarity and the critical appraisal of claims. Only by thinking critically about practice- and policy-related claims can we maximize use of the services that are effective in achieving outcomes that clients value and minimize use of ineffective and harmful ones. Critical thinking encourages professionals to think contextually, to consider the big picture, and to connect personal troubles to social issues. This requires professionals to be aware of conceptual concerns associated with the framing of problems such as depression and social anxiety as biologically based, with no attention to related psychological and environmental circumstances (see, e.g., Luyten et al., 2006). Examples of attitudes involved in critical thinking include:

Intellectual courage: Critically assessing viewpoints regardless of negative reactions. It takes courage to

tolerate ambiguity, and to face ignorance and prejudice in our own thinking. The penalties for non-conformity are often severe.

Intellectual curiosity: An interest in deeply understanding, figuring things out, and in learning.

Intellectual humility: Awareness of the limits of our knowledge, sensitivity to bias and prejudice and limitations of one’s viewpoint. No one should claim more than he or she actually knows. Lack of pretentiousness and conceit, combined with insight into the strengths and weaknesses of the logical foundations of one’s views.

Intellectual integrity: Honoring the same standards of evidence to which we hold others, practicing what we advocate, and admitting discrepancies and inconsistencies in our own thought and action.

Intellectual perseverance: The pursuit of accuracy despite difficulties, obstacles, and frustration; adherence to rational principles despite irrational opposition to others: recognizing the need to struggle with confusion and unsettled questions to pursue understanding. This trait is undermined when others provide the answers, or do our thinking for us. (Paul, 1993, pp. 470–472)

Fallacies in thinking are prevalent among researchers and professionals, as illustrated by the extensive literature describing pseudoscience and fads in the helping professions (see, e.g., Jacobson, Foxx, & Mulick, 2005; Lilienfeld, Lynn, & Lohr, 2003; Sarnoff, 2001). Indeed, flaws in the professional literature such as biased presentation of findings (e.g., hiding methodological limitations) were a key reason for the development of evidence-based practice (Gray, 2001a, 2001b). We continue to see such flaws (Altman, 2002), and increasing attention is being paid to them as well as to the negative influence of related industries such as the pharmaceutical industry (Angell, 2004; Brody, 2007; Hadler, 2004; Kassirer, 2004). Research shows that a variety of biases come into play that dilute the quality of decisions (e.g., Gambrill, 2005). Examples include the fundamental attribution error (the tendency to attribute the cause of behaviors to personal characteristics of individuals and to overlook environmental factors) and confirmation biases (the tendency to search only for data that support favored positions and to ignore data that do not). Confirmation biases may result in overlooking contradictory data (Nickerson, 1998). Failure to ask, “Is there a better alternative?” and “What are problems with my view?” encourages justification of favored views and ignoring of well-argued alternative accounts that may

be more accurate. The emphasis on gathering evidence in support of a favored position rather than exploring alternative views may hinder the discovery of valuable options.

Practitioners are influenced by the availability of material such as vivid case examples, which may be misleading rather than informative. Such biases have been found not only in the helping professions but in a wide range of other contexts as well (Dawes, 2001; Hastie & Dawes, 2001). Base-rate data are often ignored. A psychologist who sees many parents who sexually abuse their children may overdiagnose this event because of her unique situation; she may overestimate the true prevalence of sexual abuse. Resemblance criteria—the extent to which a characteristic seems to resemble or be similar to another characteristic—can also lead helpers astray (e.g., Gilovich, Griffin, & Kahneman, 2002). A counselor may assume that effects resemble their causes when, in fact, they may bear little or no resemblance to each other. Although “fast and frugal heuristics” may work fine in some situations, analytic thinking may be needed for other situations (Gigerenzer, 2005). Although intuition is an invaluable source of ideas, it is not a sound guide for testing beliefs. Oversimplifications that give an illusion of understanding may result in poor decisions such as simply labeling a behavior and assuming that one understands it. Errors in judgment may result in incorrect assumptions about the causes of problems and inaccurate predictions about suicidal potential, need for hospitalization, future recurrence of violent acts, or the results of a new service policy. Only if practitioners are aware of common biases and fallacies and develop skills and related values to counter them, such as questioning their assumptions, may biases be minimized (see, e.g., Gambrell, 2005; Skrabanek & McCormick, 1998).

Critical thinking encourages deep rather than superficial appraisal. There is a subtext of problem definition and explanation in helping professions such as social work, psychology, and psychiatry that is often unquestioned but questionable (e.g., Boyle, 2002; Houts, 2002; Szasz, 1987). This is the age of biomedical approaches to personal problems. This approach has been carried to such excess, especially on the part of the pharmaceutical industry, that there is a vigorous counterreaction because of troubling conflicts of interest (e.g., Angell, 2004; Brody, 2007; Kassirer, 2005; Lo & Field, 2009). Those who assume that psychological problems are due to brain difference often ignore well-argued critiques (see e.g., Leo & Cohen, 2003; Luyten, Blatt, VanHoudenhove, & Corveleyn, 2006; Moncrieff, 2008). Critical thinking can be of value in spotting and avoiding infor-

mal fallacies such as straw-man arguments and ad hominem appeals and in discovering methodological and conceptual problems related to claims of knowledge. It is an antidote to assuming uncritically that an entity called schizophrenia is responsible for a variety of troubling behaviors when there may be no evidence for this (Boyle, 2002). The history of the mental health industry reveals a long list of false causes for personal troubles and social problems, as well as harmful interventions to cure “mental illnesses” (e.g., Ofshe & Watters, 1994). The costs of premature acceptance of inaccurate views of problems include neglecting promising alternatives and wasting money on ineffective and harmful services and not fully funding programs found to be effective.

THE PROCESS AND PHILOSOPHY OF EVIDENCE-BASED PRACTICE AS A GUIDE

Evidence-based practice (EBP) arose as an alternative to authority-based practice, in which decisions are based on criteria such as consensus, anecdotal experience, and tradition (Sackett, Richardson, Rosenberg, & Haynes, 1997; Straus, Richardson, Glasziou, & Haynes, 2005). Although the philosophical roots of EBP are old, its blooming as a process attending to evidentiary, ethical, and application issues in all professional venues (education, practice, and policy as well as research) is fairly recent—facilitated by the Internet revolution. It is designed to break down the divisions between research, practice, and policy—emphasizing the importance of attention to ethical issues. Codes of ethics call on professionals to consider practice-related research findings and inform clients about them. EBP involves “the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual [clients]” (Sackett et al., 1997, p. 2). It requires “the integration of the best research evidence with our clinical expertise and our [client’s] values and circumstances” (Straus et al., 2005, p. 1). “Best research evidence” refers to practice-related research on the accuracy and precision of assessment, risk measures, and descriptive data, and the efficacy and safety of treatment and preventive services. “Without clinical expertise, practice risks becoming tyrannized by evidence, for even excellent external evidence may be inapplicable to or inappropriate for an individual [client]. Without current best evidence, practice risks becoming rapidly out-of-date, to the detriment of [clients]” (Sackett et al., 1997, p. 2). Steps in EBP include the following.

- (1) Converting information needs related to practice decisions into answerable questions.
- (2) Tracking down, with maximum efficiency, the best evidence with which to answer questions.
- (3) Critically appraising that evidence for its validity, impact (size of effect) and applicability (usefulness in practice).
- (4) Integrating this critical appraisal with our clinical expertise and with our (client's) unique circumstances and characteristics, including their values; and
- (5) Evaluating our effectiveness and efficiency in carrying out steps 1-4 and seeking ways to improve them in the future (Sackett et al., 2000, pp. 3-4).

EBP is an evolving process designed to attend to interrelated evidentiary, ethical, and implementation concerns. It describes a philosophy and process designed to forward effective use of professional judgment in the integration of information about each client's unique characteristics, circumstances, preferences, and actions with external research findings. "It is a guide for thinking about how decisions should be made" (Haynes, Devereaux, & Guyatt, 2002). Although the term "evidence-based practice" can be mistaken to mean only that decisions made are based on evidence of their effectiveness, its use does call attention to the fact that available evidence may not be used or that the current state of ignorance in the field may not be shared with clients. It is hoped that professionals who consider research findings and inform clients about them will provide more effective and ethical care than those who rely on criteria such as anecdotal experience, available resources, or popularity. The philosophy and process of evidence-informed practice is designed to weed out bogus claims and involve all interested parties as informed consumers (Gray, 2001a; Straus, Richardson, Glasziou, & Haynes, 2000). It is designed to increase transparency regarding the uncertainty associated with making life-affecting decisions.

EBP requires professionals to search for research findings related to important practice and policy decisions and to share what is found (including nothing) with clients. It highlights the uncertainty involved in helping clients, and it attempts to give professionals the knowledge and skills needed to handle this constructively and to help clients handle it. It is designed to break down the division between research and practice, for example, by emphasizing the importance of clinicians' critical appraisals of research reviews and developing a technology to help them to do so. "The leading figures in EBM [evidence-based medicine] . . . empha-

sized that clinicians had to use their scientific training and their judgment to interpret [guidelines] and individualize care accordingly" (Gray, 2001b, p. 26). Clinical expertise includes the use of effective relationship skills and the experience of individual helpers to rapidly identify each client's unique circumstances and characteristics and "their individual risks and benefits of potential interventions and their personal values and expectations" (Sackett et al., 2000, p. 1). It is drawn on to integrate information from these varied sources (Haynes, Devereaux, & Guyatt, 2002). Client values refer to "the unique preferences, concerns and expectations each [client] brings to a clinical encounter and which must be integrated into clinical decisions if they are to serve" the client (Sackett et al., 2000, p. 1).

EBP draws on the results of systematic, rigorous, critical appraisal of research related to important practice questions such as, Is this assessment measure valid? and Does this intervention do more good than harm? A major contribution of EBP is encouraging preparation of *systematic* reviews that are based on an exhaustive search for research findings related to a specific practice or policy question, rigorous critical appraisal of each study located, and complete transparency of criteria used to carry out this critical appraisal (e.g., see Cochrane and Campbell Collaboration Libraries). EBP is closely tied to the Cochrane Collaboration, a worldwide network of centers that prepare, maintain, and disseminate high-quality reviews of the effects of health care. The Campbell Collaboration was formed to prepare and disseminate systematic reviews in the areas of social welfare, crime and justice, and education. Preparing fragmented (incomplete) uncritical research reviews regarding practice and policy questions may result in inflated claims of effectiveness that provide misleading conclusions. Indeed, systematic reviews typically suggest less positive effects than traditional narrative reviews. Different questions require the use of different kinds of tests to critically appraise them (e.g., see Gambrill, 2005; Gibbs, 2003; Gray, 2001a). Each method is subject to certain biases. The Cochrane and Campbell Collaborations describe guidelines for preparing systematic reviews related to specific questions. Reviews are based on a search for all material, both published and unpublished, and in all languages, related to a question.

EBP and health care originated in medicine in part because of variations in services offered and their outcomes (Wennberg, 2002). In discussing the origins of evidence-based practice, Gray (2001b) notes the increasing lack of confidence in peer review, which he refers to as "feet of clay," and flaws in books, editorials, and journal articles. Examples include submission bias, publication

bias, methodological bias, abstract bias, and framing bias. There are biased estimates of the prevalence of concerns in the professional literature; there is often advocacy in place of careful weighing of evidence and reporting of related facts and figures (see, e.g., Best, 2004). Those who prepare practice guidelines may be biased by ties with pharmaceutical companies and resulting conflicts of interest (see Deyo & Patrick, 2005). In place of critical, systematic reviews of research, we often find fragmented, uncritical ones (e.g., Oxman & Guyatt, 1993).

Both critical thinking and EBP emphasize the ethical obligations of professionals. These include drawing on practice- and policy-related research and involving clients as informed participants in making decisions. They highlight the importance of being honest (transparent) concerning the evidentiary status of claims forwarded. A key implication of critical thinking and EBP is an openness to and welcoming of criticism. Feedback that facilitates learning is vital. A critical attitude, which Karl Popper (1972) defines as a willingness and commitment to open up favored views to severe scrutiny, is basic to science, which distinguishes it from pseudoscience. If we think critically about methods described in this book, we ask questions like:

- (1) Are the methods described informed by well-argued theory and by empirical findings regarding the interaction among behaviors, thoughts, and feelings and environmental events?
- (2) What is the evidentiary status of claims made? Are there systematic reviews? Are claims compatible with related research findings?
- (3) Have the effective ingredients of methods been identified?
- (4) Have moderating factors, such as certain qualities of the therapist-client relationship, been identified (see, e.g., Wampold, 2001)?
- (5) With what percentage of clients with a certain kind of problem (e.g., depression, anxiety) are methods effective?
- (6) How long do positive effects last? Have there been follow-up studies, and what is their quality?
- (7) Has the possibility of negative effects been investigated, and what has been found?
- (8) What training programs are most effective and efficient in developing related values, knowledge, and skills that contribute to successful outcomes?
- (9) Are propaganda methods avoided (e.g., ignoring well-reasoned alternatives or presenting distorted versions of disliked views)?
- (10) What personal characteristics of therapists contribute to or detract from success?

If a claim is made that a certain method is most helpful for a given kind of problem, on what basis is this claim made? Hopefully, the content in this book will accurately inform readers about the evidentiary status of assessment, intervention, and evaluation practices related to given kinds of concerns as well as describe related controversial issues. Ethical obligations to critically assess knowledge claims and the reflection of this in EBP require us to ask probing questions. The origins of EBP highlight the need for this. Let us say that we read that “A review of studies regarding ADHD shows that *x* is most effective.” We should raise the following questions: Were Cochrane and Campbell review guidelines followed? For example, was the search for relevant studies exhaustive? Was there a search of all relevant journals in all languages? Were unpublished reports sought and critically appraised as relevant? Do authors include in their research reviews studies in which findings were negative or no effects were found? Were the criteria used to review individual studies rigorous? For example, do we know for each study whether ratings of outcome were blinded (see CONSORT guidelines, Altman et al., 2001, as well as www.consort-statement.org)? Were the studies randomized controlled trials of high quality, in which there was an intention to treat analysis? Were search procedures clearly described? We do not want to get caught up in yet another fad. A fad is defined as “a therapy that is not supported by scientific evidence and that has a fairly rapid rise and fall” (Vyse, 2005, p. 5).

CHOICES

Values, knowledge, and skills related to critical thinking, including related literature on judgment and decision making (e.g., Gambrill, 2005) as well as the process and philosophy of evidence-based practice, suggest a number of interrelated choices that lie ahead.

How to Define Evidence-Based Practice

EBP is often defined as using empirically based practices (the EBPs approach) (e.g., Norcross, Beutler, & Levant, 2006). This is a much narrower view of EBP than that described by its originators (Gambrill, 2003). Such a view ignores ethical obligations such as involving clients as informed participants—sharing ignorance and uncertainty as well as knowledge. Such views ignore the unique process for helping professionals to integrate research and practice and its related philosophy, which emphasizes transparency regarding evidence gaps. Will we take

advantage of the evolving process and philosophy of EBP and related tools, such as user-friendly flowcharts and checklists for reviewing the accuracy of different kinds of research (e.g., CONSORT guidelines), and sources such as the Cochrane and Campbell databases and *Bandolier*?

How Rigorous to Be in Assessing Claims

The rigor with which practice-related research should be appraised is the subject of much controversy. Consider controversies regarding the effectiveness of multisystem therapy (Henggeler et al., 2006; Littell, 2005, 2006). The history of harming in the name of helping in the helping professions should encourage us to err on the side of caution when making claims. Otherwise, we may initiate or continue to offer services that are ineffective or harmful and lose opportunities to critically evaluate new methods.

How Transparent to Be Regarding the Evidentiary Status of Recommended Practices and Policies

Both critical thinking and EPB encourage clear description of what is done, and to what effect, including mistakes and errors. Such transparency may help professionals avoid inflated claims of knowledge that mislead clients (i.e., impede informed consent) and hinder the growth of knowledge. Terms such as *well established* and *validated* convey a certainty that is not possible (Popper, 1972). There are many opportunities to honor components of informed consent, even in nonautonomous (coercive) situations (Faden & Beauchamp, 1989; Gambrill, 2008). For example, staff could be required to give clients a written description of the evidentiary status of recommended services, the agency's record of success in achieving related outcomes, and the record of success of the staff member who will offer this service (Entwistle, Sheldon, Sowden, & Watt, 1998). Clear descriptions of goals and ongoing monitoring of valid progress indicators allow timely, informed decisions and keep clients informed about degree of progress. DUETS (www.duets.nhs.uk) was recently established to highlight the uncertainty regarding important questions.

How Systemic to Be

Evidence-based practice involves a systemic approach to improving quality of services, including educating

professionals, who are lifelong learners; involving clients as informed participants in decision making; attending to management practices and policies that influence services offered such as agency culture and climate; and considering application challenges such as the scarcity of resources (e.g., Gray, 2001b; Straus et al., 2005). A systemic approach includes helping practitioners acquire the knowledge, skills, and tools needed to deliver services within a helping framework in which research findings related to decisions are actively sought and critically appraised. Quality of service is unlikely to improve in a fragmented approach, that is, an approach that does not attend to *all* links in the system of service provision (e.g., see Greenhalgh, Robert, MacFarlane, Bate, & Kyradikou, 2004).

How to Help Professionals Integrate Research in Their Work

An extensive literature in EBP addresses the challenges of integrating research findings and practice decisions, including a description of tools of value for locating and critically appraising relevant research. A key focus in EBP is helping practitioners develop skills in critically appraising research findings related to practice and policy questions, including the adequacy of research reviews (e.g., Greenhalgh, 2006; Rennie, Guyatt, Cook, & Meade, 2008). In addition, there is a focus on helping clients develop such skills and on giving them access to needed resources, such as relevant databases (e.g., Edwards & Elwyn, 2001). Sources such as *Bandolier* produce a steady stream of material concerning the effectiveness of common practices and highlight common methodological concerns in practice-related research, such as unblinded rating of outcomes and lack of random assignment of subjects.

Helpers cannot empower clients if they are not empowered themselves (e.g., are not informed about research findings related to decisions they make or do not have the knowledge or resources needed). A psychologist cannot inform her clients about the risks and benefits of recommended methods (including assessment, intervention, and evaluation methods) unless she is well informed. The degree to which professionals can empower clients thus depends in part on the extent to which their knowledge, skills, and other resources match what is needed. Accurately estimating this match is one important way that clinicians take responsibility for their decisions. Fox and Swazey (1974) suggest that there are three major causes of failure: (1) lack of available information (no one knows the answer),

(2) failure to get it, and (3) failure to recognize one's own ignorance. Different sources of failure and uncertainty suggest different remedies.

How Much Attention to Give to Individual Differences

Decisions must be made, together with the client, about whether research findings apply to a particular client. Different clients may weigh potential risks and benefits differently. Clients differ in their values and expectations. "Expertise [proficiency and judgment that individual practitioners acquire through experience and practice] is reflected in many ways, but especially in more effective and efficient [assessment] and in the more thoughtful identification and compassionate use of individual [clients'] predicaments, rights, and preferences in making . . . decisions about their care" (Sackett et al., 1997). Evidence-based practitioners transform information needs related to decisions about a particular client into answerable questions that guide a literature search (e.g., Gambrill, 2005; Gibbs, 2003).

How Much Attention to Pay to Minimizing Harming in the Name of Helping

Avoiding use of interventions found to be harmful and identifying and minimizing errors, accidents, and mistakes will decrease harm. A careful review of the circumstances related to mistakes allows us to plan how to minimize those that are avoidable. Research regarding errors in medicine shows that latent causes (e.g., quality of staff training, agency policy) contribute to mistakes and errors (Reason, 2001). Each individual and agency should have a system for identifying, tracking, and reporting errors; identifying their causes and consequences; and using the information gained to minimize avoidable errors that diminish quality of services.

Whether to Blow the Whistle on Pseudo Science, Quackery, Fraud, and Related Propaganda Tactics

Quackery refers to the for-profit promotion and marketing of untested, often worthless, and sometimes dangerous health products and procedures, by professionals and others (Bausell, 2007; Young, 1992). Indicators include the use of anecdotes and testimonials to support claims and secrecy (claims are not open to objective scrutiny). Fraud is the intentional misrepresentation

of the effect of certain actions to persuade people to part with something of value (e.g., money). Fraudulent claims (often appealing to the trappings of science) may result in overlooking effective methods or being harmed by remedies that are supposed to help. Transparency of what is done to what effect, critical appraisal of claims, and honoring ethical obligations to clients call for blowing the whistle on pseudoscience, fraud, quackery, and propaganda in professional contexts. Censorship of competing views and critiques of preferred views misleads rather than informs. It prevents discovery of promising alternatives.

IN CONCLUSION

There are many indications that critical thinking and its reflection in EBP do not thrive in the helping professions. This can be seen in educational, practice, and policy venues. Methods of unknown effectiveness continue to be used. A key reason is a preference for authority-based practices, for example, basing recommendations on tradition or popularity, and related incentives such as status and money and saving time in learning new methods. The history of harming in the name of helping and the failure to abandon ineffective methods and to offer clients effective methods shows the importance of acquiring and using critical appraisal skills. Concerns in our field are also concerns in other professional areas, and we can draw on developments in this wider area, such as the process and philosophy of EBP, to honor professional codes of ethics. We live in a society in which grandiose claims of knowledge about what is true and what is not rule the day, even in publications that portend to critically appraise claims, such as the *Evidence-Based Practice Manual* by Alberts and Yeager (2004; see critique by Carlstedt, 2005). This tendency is part of a culture in which public relations and advertising flood us with images and staged events designed to persuade us to act in certain ways (Ewen, 1996).

The purpose of propaganda is to encourage beliefs and actions with the least thought possible. Certainly propaganda is not the sole cause of harm and ineffective treatment. But it is a major avoidable source. It enters at many points during professional education and in practice, including continuing education programs required for licensure. For example, pharmaceutical companies fund a large portion of the continuing education programs offered for physicians. Influence from these companies are passed on to clients and patients. Material presented in such programs is repeated

in pharmaceutical ads directed toward professionals as well as consumers via direct-to-consumer advertising on television, in magazines and newspapers, and on the Internet. Propaganda in the media and in the professional literature interact with self-propaganda such as wishful thinking as well as confirmation biases (our tendency to search only for material that supports our views and to ignore competing views (Nickerson, 1998). The history of harming in the name of helping illustrates the need to help professionals recognize propaganda in the guise of scholarship. It is time to pay more attention to propaganda in the helping professions, including venues such as professional journals and education programs. The stakes are high in terms of lost opportunities to make well-informed decisions by integrating views and data from multiple perspectives, as this may be needed to make choices that help clients. Some medical schools now offer courses designed to alert students to propaganda methods that pharmaceutical companies use to promote drugs (Wilkes, & Hoffman, 2001; Wofford & Ohl, 2005).

Critical thinking values, skills, and knowledge, and the evolving process and philosophy of EBP are suggested as guides to making ethical, professional decisions. Both encourage helpers to base decisions on well-reasoned judgments and honor ethical obligations. Advantages of both in relation to ethical practice include an emphasis on transparency of what is done, and to what effect, and integration of research and practice. Being informed about different kinds of research and their advantages and disadvantages, including biases that result in misleading results, will help both clients and professionals draw on practice- and policy-related research in making decisions. This kind of research savvy is closely related to honoring ethical obligations to clients. Sources such as the Cochrane and Campbell databases and other avenues for diffusion of knowledge as well as ignorance, such as DUETS, together will help practitioners and clients to acquire critical appraisal skills and will make it increasingly difficult to mislead people about "what we know." It will be more difficult to ignore questions and well-argued alternative views, lack of evidence regarding services used, and harm done in the name of helping. It should be easier to locate programs that have been critically tested and found to help clients and avoid harm. Understanding the nature and prevalence of propaganda and its aims and consequences, and keeping critical thinking skills well honed, and will be useful in spotting evidence gaps (gaps between what is claimed and what has been found via critical inquiry).

Clinical Trials: A Primer for Clinicians

Itay Perlstein
Eric J. Olson

INTRODUCTION AND HISTORY

Probably the most important hurdle to establishing credibility or belief in the efficacy of a therapeutic approach (medicinal or non-medicinal), as well as confirm the basis for a particular theory, is confirmation through research or testing. Testing can take on many forms, depending on the topic; however, this chapter will focus on testing among the human element through clinical studies or trials.

Simply defined, clinical trials are research studies in which human beings are the recipients of a therapeutic modality or are used as the variable being influenced by a particular action or activity. Critical to the health care industry are clinical trials that test products or approaches to establish their safety and efficacy. Studies of an investigational tablet given as a single dose to a dozen healthy young volunteers and a marketed drug given for a period of two years to 25,000 patients in 15 countries would both be considered clinical trials that could, depending on the level of knowledge about the therapy, qualify as testing for safety and efficacy. These examples serve as a useful illustration of the breadth or scope of clinical trials.

In the first example, the tablet may contain a new chemical entity that has never been administered to a human being. In this case, even a single dose (albeit most likely a very low dose level) is considered a sig-

nificantly large risk, and acute safety can be assessed prior to development. It is conceivable that a measurable pharmacologic action would be observed with this single dose as well. Additional tests from a single dose could also inform the investigator as to the level of medication that made it into the individual's blood and allow relationships to be inferred between exposure and effect. In the second example, the medication is most likely perceived to be safe based on smaller, shorter duration studies, but the true evaluation of safety (as well as efficacy) requires administration to a very large population of individuals to adequately assess safety for events that may only occur on a 1-in-1,000 basis. In addition, the large study may also serve to determine the ability of the therapeutic to reduce mortality in a population of very sick patients.

In both cases, the intent of the data collected for the drug varies, depending on the hypothesis or objectives; however, ultimately the goal is to treat or prevent a pathophysiological condition or disease state. More specific to the field of psychology, clinical trials may also be conducted to promote the well-being and personal development of already physically healthy individuals.

In any type of scientific trial, the believability of the data is directly related to the method of conduct. It has become a matter of dogma that for data to be believable, certain scientific rigor must be employed. The basic algorithm includes the premise that the

trial is conducted in the most objective manner possible, with the expectation that the study will be reproducible. That is, if another investigator conducted the study under the same conditions, similar results would be observed. While the popular approach commonly known as the scientific method has its roots in the work of Aristotle in ancient Greece and the Arabian physicist Alhazen, known as “Ptolemy the Second,” the contemporary approach of observation, hypothesis, experimentation, and interpretation of data resulting in a conclusion finds its source with Roger Bacon, a 13th-century Franciscan friar. It was his communication of a repeated process of verification that could be duplicated by others that became the foundation of what some call credible science. However, methodology aside, application of the scientific method takes on a different burden when conduct of the method involves human subjects.

While many trials in the scientific field may not have to contend with consideration of risk or life-threatening procedures, clinical trials involve some underlying level of risk. An investigator must continually take into consideration the perceived benefit and weigh it against the potential risks. In some cases, the methodology may pose a significant risk to a subject's well-being or, at the most extreme, his or her life. It is because of the risk-to-benefit consideration that clinical trials have evolved from the emotionless application of the scientific method to the level of regulation experienced today. For basic ethical reasons, each stage of the process associated with clinical trials has elements that are subject to the scrutiny of external audit. These include the elements of planning, proper conduct, and reporting requirements. In the case of pharmaceutical trials, specific bodies of governance (the U.S. Food and Drug Administration, the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use in the United Kingdom, the European Medicines Agency, the Pharmaceuticals and Medical Devices Agency in Japan, etc.) provide minimal standards for the proper conduct of clinical studies that are enforceable; failure to follow them accordingly can result in legal repercussions. Clinical trials need to meet the standards determined by local, national, and international regulation that ensure the safety and welfare of the individuals who participate in the trial.

In the health care industry, the process and details of proper clinical trial conduct are now well established. The goal of this chapter will be to provide a general overview of these basic principles. The first part of this chapter will concentrate on the basics of clinical

trials. The rationale for conducting the trials will be introduced, and the different types of trials and designs will be discussed. The second part of the chapter will provide commentary on three key questions that must be answered in any clinical trial: What end points are measured during the trial? What is considered a significant clinical effect? And what will be the impact of the results after they are reported? These questions will be covered through discussion of end points, statistical considerations, and an introduction to concepts of evidence-based medicine.

BIAS REDUCTION PRINCIPLES: THE RANDOMIZED, DOUBLE-BLIND, CONTROLLED TRIAL

A basic premise of objective research is that bias or elements of subjectivity that could influence the outcome of an experiment must be minimized. The scientific method arranges an environment for experimentation that facilitates the reduction of bias implicit in its approach (i.e., result in the duplication of data if performed by another scientist); however, other principles for reduction of bias are not included in the basic scientific method formula. These principles are conveniently applied within the design of the study.

It is implicitly clear that clinical trial results should be accurate and reliable in order to provide a valid and unbiased assessment of the true efficacy and safety of the tested treatment. Bias is considered any deviation from the true value of efficacy and safety. The investigator should make every attempt to avoid bias. It should be noted that most biases are caused by human errors, so it is imperative to understand potential sources of error.

There are reasons for bias in different parts of the clinical trial. Some common examples are summarized in Table 3.1.

Three fundamental principles (control, randomization, and blinding) are commonly utilized to reduce the level of bias introduced into a study and are employed prior to initiation of the study or as a critical component of the design.

The basic premise of a controlled study is that participants are divided into different groups and treated to the extent possible (depending on the therapy and environment) in an identical manner. The most fundamental controlled study consists of two groups (or arms). The first arm generally receives an active treatment (or the therapeutic agent that is being tested). The second

3.1

Major Sources of Bias in Clinical Trial

PART OF THE STUDY	POSSIBLE REASON FOR BIAS
Patient selection	Sampling of the target population that would inherently skew the data
Allocation of patients to treatments	Bias in favor of the new treatment (drug favoritism) Bias against the new treatment (ethics)
Measurement of response	Choice of responses that are available Sensitivity of the instrument that records the data Human subjectivity component

group (the control group) is identical but does not receive the treatment in question. Researchers can then compare the results between the groups to determine if there is a change in outcome due to the presence of the active treatment. The control arm can also serve as a barometer to determine if a group of individuals (i.e., the non-treated group) will experience any changes due to study conditions. The control arm is commonly titled the placebo arm, in reference to drug trials in which a tablet that looks exactly like the active medication is administered. In other cases, and very commonly in medical research, the control arm is simply providing the accepted standard of care while the active treatment arm receives the treatment in addition to or on top of the accepted standard of care. If there is more than one active treatment, the control arm can be referred to as an active control. In this case, the researcher may be looking to answer the question, “Which treatment works better?” to optimize patient care.

The principle of the controlled study was introduced in 1767 by Dr. William Watson of the Founding Hospital in London in a smallpox pediatric inoculation trial (Boylston, 2002). In this study, he used what was called a non-treatment concurrent control. He tried to answer two basic questions: (1) What is the best source of inoculums? and (2) Did mercury provide any clinical benefit when used as a pre-treatment? The study population consisted of young boys and girls with

similar diet, clothing, sleeping location, and the like. They were inoculated at the same time and physical location. Therefore, the only differences between the groups were (1) the kind of pre-treatment administered (mixture of mercury and jalap, a laxative; senna and syrup of roses, a mild laxative; or no pre-treatment) and (2) the source of inoculums (early lesion from a patient with naturally acquired smallpox or mature lesion from inoculated patient).

Interestingly, although British sailors had incorporated limes in their food stocks as early as the late 1700s, the basis for scurvy and its prevention was unknown. This set the stage for another famous example of trial that could be considered controlled. In 1847, British naval surgeon James Lind used this approach to test for a preventive for scurvy. While out at sea for several weeks, many sailors became sick with scurvy (which is now known to be caused by vitamin C deficiency). Lind selected 12 sick sailors with similar conditions and divided them into pairs. They all received the same diet, and in addition, each pair of men was treated with one of the following popular scurvy treatments:

A quart of cider

25 drops of elixir vitrial (weak acid)

2 spoonfuls of vinegar

A pint of sea water

Spicy nutmeg paste and a drink of barley water

2 oranges and 1 lemon

The duration of the treatment supply lasted six days but provided a clear outcome: the condition of the men who received the oranges and lemons demonstrated significant improvement—so much so that one of the sailors returned to duty, while the other sailor who received the oranges and lemon was appointed as a nurse to the remaining men. Out of the six active treatments, Lind was able to prove that citrus fruits were the most effective anti-scurvy medicine/preventive. While these examples would not be considered well-controlled trials today, both illustrate the basic characteristics of a controlled study, in which participants are divided into different groups and treated similarly, except for the drug or treatment being studied. The outcome in both cases had a significant impact on the standard of care or preventive medicine (Dunn, 1997).

While today a controlled study is the gold standard for trials with believable results, until the 1940s the need for control group was not self-evident. Many of the early clinical studies evaluating penicillin were

conducted without a control group. Even in the early 1970s uncontrolled clinical trials were not uncommon. Two main reasons were provided to justify the absence of control group: (1) the belief that a large treatment group did not require a comparison group and (2) an ethical argument that withholding the experimental treatment would harm the patients. To a certain extent, this logic still holds true, depending on the objective and the end points being measured in the study. For instance, in the case of penicillin, the absence of an infection is relatively clear and such a finding would be indisputable. However, how can one be certain that it is the penicillin and not something in the compounding of the tablet that is responsible for the elimination of the bacteria? A tablet formulated without the one component being questioned (penicillin) can satisfy the questioner. A familiar example illustrating this concept involves the discovery of valproic acid, which is currently administered as an anticonvulsant, notably for those suffering from epilepsy. Valproic acid was used in the laboratory setting for many years as an inert solvent to solubilize organic compounds before it was discovered that anticonvulsants dissolved in valproic acid showed greater anti-seizure effects. The acid was subsequently tested on its own and eventually approved in France for use in epilepsy.

Today it is clear that controlled studies provide the most convincing medical evidence. Aside from questions related to formulation or unexplained effects inherent to the study, the tested therapeutic treatment holds its own inherent risks. Therefore, the concern becomes more a matter of ethics, and controlled studies are regarded as a means to reduce the size of the studies to minimize undue exposure of humans. This is particularly useful when the end point that is being measured has a great deal of variability, has a low level of detectability, or is subject to drift over time. In some cases, if the signal is difficult to detect, an active control with a predictable effect may be used as a reference point, as in the case of moxifloxacin, which is commonly used in studies designed to determine if a compound influences the QT wave in cardiac rhythms.

With respect to the ethical argument, many of the studies are currently conducted as crossover trials where the same subject is treated in alternating periods during the study, with the active test drug during one period of time and with placebo for another period of time. The statistical power of crossover designs can dramatically reduce the number of individuals needed as test subjects. Furthermore, in severe diseases such as cancer and AIDS, when new alternative drugs are available, studies are conducted with an active control group (active comparator) rather than a placebo. It is

quite obvious that in life-and-death situations, there is sometimes no ethical basis for not providing some level of treatment. The tested drug is therefore compared to the accepted standard of care.

Random Allocation

Roland Fisher is credited with establishing the basic fundamentals of random allocations circa the mid-1920s. Fisher (1925), who worked in agricultural research, randomly allocated new seed formulations and new fertilizer compositions into similar sized plots of ground. Each plot had the same chance of receiving the new or standard/existing treatment. The resulting random distribution of treatments ensured that any difference in plant growth would be attributed to the treatment, and not other characteristic such as soil content and moisture, and insects.

The concept was widely accepted and deemed a reasonable way to resolve scrutiny with respect to the data. Thus, random allocation principals were quickly adopted in other research venues, and the first randomization experiment was conducted in 1923. Finally in 1931, the first randomized enrollment of patients in a trial was performed in patients diagnosed with tuberculosis. In this case 24 institutionalized individuals were recruited. They were matched into 12 pairs based on their conditions. For each pair of patients, a coin was flipped to determine which patient would receive the active drug and which would receive the control treatment (Amberson, McMahon, & Pinner, 1931).

While the principle of random allocation at the time of entry is considered a pure form of randomization, today the allocation schedule uses the rules of probability to determine what therapy the patient receives and is generated via automated means in advance. This gives an investigator the ability to enroll a minimal yet sufficient number of subjects into each arm of a trial. The coin-flip method could theoretically result in a lopsided distribution of subjects into a particular arm. As unfavorable as this might be to an investigator, someone who gambles for a living could conceive of dice rolls that consistently resulted the same way as lucky. Fortunately, in research, one does one's best to ensure this does not happen ahead of time.

Tables 3.2a and 3.2b provide examples of common random allocation schedules. Table 3.2a presents an example of randomization used for a study where three treatments are studied: the tested drug (Drug A), the active control (Drug B), and the placebo are given on three different occasions. Each subject is treated three times and receives all three treatments in a dif-

ferent order. Table 3.2b presents a simplified example of a 6/2 randomization allocation schedule used for a dose-escalating study. While there are five different treatments (four doses of drug and a placebo), each subject is treated with only four treatments (a placebo and three doses of drug; indicated by plus signs). Each time the group is treated (arm), six subjects are allocated to receive the drug treatment and two are allocated to be treated with placebo (6/2). At the end of the study, six subjects were treated in each dose level of the drug treatment and eight subjects were treated with placebo. By choosing this kind of design, the investigator is able to collect a sufficient amount of data while “saving” a full study arm, thus shortening the study duration, accelerating the decision process, saving resources, and most importantly reducing the number of subjects exposed to the experimental drug.

Blinding

While the purpose of randomization is to ensure that groups of patients with similar characteristics are randomly and evenly distributed between various treatment arms, the purpose of blinding is to ensure the patients are unaware of their specific treatment, thereby limiting the chance for patients to influence the results.

For example, if a patient knows that he is being treated with placebo, it is conceivable that based on his

belief in the ineffectiveness of the placebo, he might provide feedback in line with his expectations or simply behave differently. The observer therefore ends up with data that either is deceptive or cannot be rationally interpreted. On the other hand, patients treated with the experimental drug may be more inclined to provide positive reports to the investigator or act according to their personal expectations. Both cases will result in a biased conclusion by the investigator about the true effect of the drug.

Therefore, it is important to make sure that the patients involved in a single-blind study do not know the nature of the treatment that they have been assigned. While the blinding does not suppress the potential for inappropriate beliefs or behaviors among patients, it distributes it equally among the groups.

Although blinding of patients serves a critical purpose in the conveyance of data, the influence of the treating physicians and other health care professionals taking part in the study may also skew the study results. The physicians, for example, may (1) have the tendency to treat sicker patients with the active treatment (which is presumably more helpful) and (2) provide extra care to patient treated with placebo. In order to prevent such bias, a second level of blinding may be introduced: the double blind. In the double-blind study, both the patient and the physician do not know which treatment is administered to which patient.

3.2a

Example of 3 Treatment Arm Study

PATIENT	SUBJECT ID	ALLOCATION		
		1	2	3
Patient 1	4	Drug A	Drug B	Placebo
Patient 2	1	Drug B	Placebo	Drug A
Patient 3	6	Placebo	Drug A	Drug B
Patient 4	5	Drug B	Drug A	Placebo
Patient 5	2	Drug A	Placebo	Drug B
Patient 6	3	Placebo	Drug B	Drug A

3.2b

Example of a Simplified 6/2 Design

PATIENT	SUBJECT ID	ALLOCATION/ARM			
		DOSE 1 (1 mg)	DOSE 2 (5 mg)	DOSE 3 (15 mg)	DOSE 4 (30 mg)
Patient 1	4	Placebo	+	+	+
Patient 2	1	+	Placebo	+	+
Patient 3	7	+	+	Placebo	+
Patient 4	5	+	+	+	Placebo
Patient 5	8	Placebo	+	+	+
Patient 6	2	+	Placebo	+	+
Patient 7	6	+	+	Placebo	+
Patient 8	3	+	+	+	Placebo

Stratification

There are times when it is important to take one extra step of precaution beyond randomization to ensure proper distribution of subjects across treatment groups. Prior to randomization, the investigator ensures that the number of patients assigned to the experimental and the control arms is balanced in respect to important attributes such as gender, age, race/ethnicity, or disease state. The stratification process is especially important when one of these variables is known to have large impact on the measured outcome. If adequately planned, stratification allows the investigator to perform subgroups analysis at the end of the study in order to identify the subgroups that will gain the most from the treatment.

CLASSIFICATION OF CLINICAL TRIALS

The initial classification of clinical trials has generally depended on the control that the investigator has over the subjects and/or the treatment instituted and is bro-

ken down simplistically into observational and interventional approaches.

Observational studies are those in which the investigator does not have control over the treatment or activity that the patients are assigned to. He or she can only observe the subjects or the outcomes.

The second type of study is the interventional study. In these studies, the investigator provides a form of treatment to the subjects with drug or other intervention and measures the outcome on patients' health, usually comparing it to the outcomes following treatment with the accepted standard of care or to no treatment. The most common type of interventional study is the randomized controlled trial, in which the subjects are randomly assigned to receive either a study treatment or placebo (or no intervention). It is important to remember that in interventional trials, the treatment may or may not utilize a drug substance. In the case of psychology testing, the treatment is often a modality/approach or involves the elimination of an environmental factor.

Clinical trials may also be broken down into different types of categories based on differing characteristics or based on purpose. Notably the U.S. National

Institutes of Health and the National Cancer Institute have classified trials into several categories according to the purpose of the study, as follows (ClinicalTrials.gov, 2008; National Cancer Institute, 2006).

Prevention trials are designed to test new approaches, such as medications, vaccines, vitamins, and other supplements and lifestyle changes that the investigators believe may prevent or lower the risk of a certain disease. Most prevention trials use healthy subjects who have not had the disease in question. Some trials are conducted with people who have had a particular disease and want to prevent recurrence or reduce the chance of developing a new variation of the same disease, as is sometimes seen in oncology.

Screening trials study ways to detect certain diseases or health conditions as early as possible. These trials are usually conducted with people who have the potential to develop the disease but have not yet developed symptoms. Obviously, the earlier a disease is identified, the greater the potential treatment arsenal that may be available when the disease becomes manifest. Genetic investigation for the predisposing DNA sequences linked to Alzheimer's and analyses of markers denoting predisposition for development of atherosclerosis are two well-known examples. Such studies are often conducted to determine if finding a type of cancer before it causes symptoms decreases a person's chance of dying from the disease.

Diagnostic trials are conducted to find better tests or procedures for the diagnosis of a particular disease or condition. Diagnostic trials usually include people who have already shown signs or symptoms of the disease.

The largest body of studies belongs to the category of treatment trials. These trials test experimental treatments such as drugs, devices, surgery, and radiation. The treatment study may also test combinations of treatments or new ways of using standard treatments. The intention is to answer specific questions about the treatment or to evaluate its effectiveness. While the goal of many studies is to determine the effectiveness of a treatment in sick patients, some studies are conducted in healthy volunteers. Treatment trials in healthy volunteers are generally used to determine the initial safety and tolerability of the compound before it is provided to sick individuals. This stepwise approach is deemed a safer way to progress, as particular side effects could be harmful to a patient. In the case of treatments for serious illnesses, when no effective treatment is available, experimental medications may be immediately tested in patients as a possible means for survival. In these cases, the potential benefit far outweighs the risks, as the patient's prognosis may otherwise be death.

Quality-of-life/supportive care trials explore ways to improve the comfort and quality of life of individuals with chronic illness. The type of trial may involve investigation of symptoms that are a result of the illness itself or the treatments commonly used for the illness. Since almost every drug treatment has some level of potential for adverse events or aggravating side effects, many of the studies in this category investigate the possibility of reducing the adverse event profile of the medication or the impact the effect has on the patient's quality of life, for example, the reduction of nausea associated with cancer treatments.

Genetic studies are usually not stand-alone studies. These studies are sometimes conducted as part of another clinical trial and focus on how genetic components may affect the detection of the disease or the response to a specific treatment. This type of study is becoming more common as researches gain a better understanding of the implication of genetics on the effectiveness or side effect profile of many medications. Ultimately this information can be utilized to better administer the proper medication to patient populations and may be expected to be efficiently applied in the future as technology advances.

PHASES

Since many clinical studies run with the intent of supporting a regulatory filing to regulatory agencies such as the FDA and the European Medicines Agency, clinical trials are often categorized by their phase of development. The most common categorization is simply numbered phase I, phase II, phase III, and phase IV. These phases have become commonplace across most, if not all, regulatory authorities and are recognized to have similar definitions from country to country. In a general manner of speaking, the first two phases are considered learning phases, and phase III is considered the confirming phase. This confirmation takes place in pivotal studies, which are required when one wishes to file a new medication for marketing. In these studies, during phases I and II the investigators try to understand the pharmacokinetics and pharmacodynamics of the drug.

Phase I

Research at this stage of development includes the first administration/application in humans as single doses and subsequent movement toward short-duration repeated dosing. Often, during this phase a small number (20–80) of healthy volunteers are enrolled and the safety

of the compound and the components of pharmacokinetics (disposition, absorption, metabolism, elimination, etc.) are studied. Usually, the process begins with very small doses and slowly escalates (single doses first) and subsequently the process is repeated with repeated dosing. If possible, efforts are made to examine the mechanism of action or some type of pharmacologic effect (pharmacodynamics), and sometimes a relationship between the drug exposure and pharmacodynamic effect is established. Once the safety, the pharmacokinetics, and the pharmacodynamics (if possible) are understood, the next step is to confirm some level of activity in the targeted patient population in early phase II. Due to the safety concerns involved in phase I studies, guidelines for conducting different phase I studies have been published by different regulatory agencies. Of interest regarding safety are studies for compounds that are administered for the first time in humans. Following some unfortunate events surrounding a clinical trial in the United Kingdom in 2006, in which several subjects suffered a severe adverse reaction, specific guidelines were published by the European Medicines Agency (2007) to identify and mitigate risks for “first time in man clinical” trials.

Phase II

Generally phase II begins with the first administration/application of a therapy in the patient population and is a controlled study of some type (active or placebo). The hypothesis to be tested may be that drug x will lower blood glucose in a population of patients with diabetes or that a particular therapeutic approach will work to alleviate symptoms of obsessive-compulsive behavior. At times the first patient study is called a proof of concept. Throughout phase II, the investigator evaluates the therapeutic modality to hone either the dose or the timing/application of the approach. Once the investigator generates enough pharmacodynamic data that demonstrate clear efficacy profiles as well as short-term safety at the doses used (or no untoward negative impact of the therapy), he or she is ready to enter the confirmatory phase, also known as phase III.

It is important to note a valuable principle used at this stage—that is, the importance of understanding the lowest level of dose or intervention needed to achieve maximum efficacy (the dose-finding stage). The basis for this principle is that it should be the investigator's ultimate goal to provide the therapy as safely as possible. Theoretically, the lowest dose level or intervention should reduce the potential for harm or untoward effects that may only manifest after years of administration to

thousands or millions of patients. Therefore, it is the responsibility of the investigator to explore and learn as much as possible prior to phase III or ultimately entry into the marketplace.

Phase III

The investigator enters phase III with the intent to confirm the therapeutic benefit of the drug or approach in well-controlled studies. The benefit is weighed against the overall risk of the therapy via extrapolation of the observed safety and efficacy results. One could expect to see hundreds to thousands or even tens of thousands of patients enrolled as the investigators develop the benefit-to-risk profile and ultimately determine what comments will be made in the package insert (label) of the therapeutic.

Phase IV

A study that includes a fourth phase is generally called a post-marketing trial. Generally, this term is applied to pharmaceutical studies that are conducted to continue safety and efficacy surveillance or to compare a therapeutic to other marketplace competitors. In some case the design of these studies are agreed upon with the regulatory agency prior to marketing of the drug. In certain circumstances, efficacy data or safety findings in these studies have led to the removal of a drug from the market.

THE PROTOCOL

The concept of the protocol is straightforward; it is the blue print or the study outline on which the clinical trial is based. It is carefully designed to safeguard the health of the participant as well as answer specific research questions. This document describes the objectives and design of the clinical trial and provides details about the organization and conduct of the study, including the way the results will be analyzed.

Most view the protocol essentially as a contract between the investigator or sponsor and any individuals connected to the study. The protocol can be quite long, depending on the sponsor and nature of the study, but includes the names of the investigator(s), ethics committees, regulatory agencies, and contracted research organization or laboratories, and finally the most important component—the patient. The investigator must always remember that no matter how complex the design of a clinical trial is or what style or approach is taken, the pa-

tients or volunteers who participate in the study are entrusting their own well-being to the care of the investigator. No level of preparation or scrutiny is too much, given the nature of the possible risks posed by some trials.

In brief, the protocol describes what types of patients may enter the study, the schedules of tests and procedures, the drugs and dosages that will be used, and the length of study, as well as the outcomes that will be measured. Each person participating in the study must agree to the rules set out by the protocol. When a clinical trial is a multi-center trial (i.e., it is conducted in several locations), the protocol allows investigators at every site to perform the study exactly in the same way. In that way the data from all sites can be combined and analyzed.

The specific content of each section of a protocol is not reviewed in this chapter due to the variety of approaches that investigators and sponsors elect when authoring these components. Readers interested in expanding their knowledge of clinical trial protocols are encouraged to read Chow and Liu's *Design and Analysis of Clinical Trials* (2004) and Piantadosi's "Importance of the Protocol Document" (2005). The formats of clinical trial protocols in most countries are relatively similar and generally follow some standardized outlines in accordance with the good clinical practices guidance issued by the International Conference on Harmonisation (U.S. Food and Drug Administration, 1996, pp. 38–42). A general format for a table of contents and a brief description of the different sections are presented in Table 3.3.

END POINTS IN CLINICAL TRIALS

An end point is what the study is trying to measure and is determined before the study begins. The results of the study indicate the ability of the therapeutic to affect the end point of concern, the number of patients who reached the predetermined end point out of all the patients enrolled in the study, or the number of patients in the controlled group who reached an end point versus the number of those in the treatment group who did so. There are three different types of end points that are commonly measured in clinical trials: efficacy, safety, and pharmacokinetic end points.

Efficacy End Points

Different types of efficacy end points are measured in clinical trials. Efficacy (commonly referred to as "effect") is the clinical effect that the drug/treatment has on the disease symptoms or disease progression. Regardless

of the effect's origin (physiological or psychological/behavioral), efficacy end points are categorized according to the study population (patients or healthy volunteers) and by their relation to the clinical outcome: end points measured in patient populations during late-phase efficacy studies are commonly used to evaluate whether a drug provides a clinical benefit (outcome) or an improvement in symptoms. In early-phase studies, which are mainly conducted in healthy volunteers, the investigator is not able to examine the effect on a disease or pathology; therefore the focus is on identifying evidence of biological activity through measurement of biomarker end points, with the hope that this measure will be able to predict (i.e., act as a surrogate for) the clinical outcome in a patient population.

Outcome End Points

An outcome end point is a characteristic or variable that reflects how a patient feels, functions, or survives. Outcome end points that are measurable are the most compelling evidence of a therapeutic effect. An outcome study tries to answer the question "Did the subjects being treated live longer, live better, or have fewer problems?" One type of outcome study evaluates therapeutic benefit on the mortality and morbidity related to a particular disease. While survival studies are relatively long, other outcome end points, such as common disease symptoms or disease progression, may be measured more quickly. For example, for people experiencing insomnia, a drug effect may be an increase in total sleep time or a decrease in time to sleep onset. An example of effect on disease progression is the percent reduction in cognitive deterioration. Determination of efficacy end points may be subjective (e.g., they may be self-reported, as in pain or sleep evaluation questionnaires) or objective (e.g., lung function testing in asthma patients).

While outcome measurements produce evidence for therapeutic effect, they require relatively long-term clinical studies (may continue for several years), and enrollment of many patients (thousands of patients or more) may be required.

Surrogate End Points (Directly Related to Disease Outcome or Risk)

Because a number of diseases develop over a long period of time, it may not be possible to carry out the study for the duration necessary to see a statistically meaningful difference in the incidence of disease among study subjects in the treatment and control groups. A surrogate end point is "a laboratory measurement or physical sign

3.3

Example of Table of Contents

1 GENERAL INFORMATION

- 1.1 Protocol title, protocol identifying number, and date. Any amendment(s) should also bear the amendment number(s) and date(s).
- 1.2 Name and address of the investigator, sponsor and medical monitor (if other than the sponsor).
- 1.3 Name and title of the person(s) authorized to sign the protocol and the protocol amendment(s) for the sponsor.
- 1.4 Name, title, address, and telephone number(s) of the sponsor's medical expert (or dentist when appropriate) for the trial.
- 1.5 Name and title of the investigator(s) who is (are) responsible for conducting the trial, and the address and telephone number(s) of the trial site(s).
- 1.6 Name, title, address, and telephone number(s) of the qualified physician (or dentist, if applicable) who is responsible for all trial-site related medical (or dental) decisions (if other than investigator).
- 1.7 Name(s) and address(es) of the clinical laboratory(ies) and other medical and/or technical department(s) and/or institutions involved in the trial.

2 BACKGROUND INFORMATION

- 2.1 Name and description of the investigational product(s).
- 2.2 A summary of findings from nonclinical studies that potentially have clinical significance and from clinical trials that are relevant to the trial.
- 2.3 Summary of the known and potential risks and benefits, if any, to human subjects.
- 2.4 Description of and justification for the route of administration, dosage, dosage regimen, and treatment period(s).
- 2.5 A statement that the trial will be conducted in compliance with the protocol, GCP, and the applicable regulatory requirement(s).
- 2.6 Description of the population to be studied.
- 2.7 References to literature and data that are relevant to the trial, and that provide background for the trial.

3 TRIAL OBJECTIVES AND PURPOSE

A detailed description of the objectives and the purpose of the trial.

4 TRIAL DESIGN

The scientific integrity of the trial and the credibility of the data from the trial depend substantially on the trial design. A description of the trial design should include:

3.3

Example of Table of Contents *(continued)*

- 4.1 A specific statement of the primary endpoints and the secondary endpoints, if any, to be measured during the trial.
- 4.2 A description of the type/design of trial to be conducted (e.g., double-blind, placebo-controlled, parallel design) and a schematic diagram of trial design, procedures, and stages.
- 4.3 A description of the measures taken to minimize/avoid bias, including (for example):
 - (a) Randomization.
 - (b) Blinding.
- 4.4 A description of the trial treatment(s) and the dosage and dosage regimen of the investigational product(s). Also include a description of the dosage form, packaging, and labeling of the investigational product(s).
- 4.5 The expected duration of subject participation, and a description of the sequence and duration of all trial periods, including follow-up, if any.
- 4.6 A description of the “stopping rules” or “discontinuation criteria” for individual subjects, parts of trial, and entire trial.
- 4.7 Accountability procedures for the investigational product(s), including the placebo(s) and comparator(s), if any.
- 4.8 Maintenance of trial treatment randomization codes and procedures for breaking codes.
- 4.9 The identification of any data to be recorded directly on the CRFs (i.e., no prior written or electronic record of data), and to be considered to be source data.

5 SELECTION AND WITHDRAWAL OF SUBJECTS

- 5.1 Subject inclusion criteria.
- 5.2 Subject exclusion criteria.
- 5.3 Subject withdrawal criteria (i.e., terminating investigational product treatment/trial treatment) and procedures specifying:
 - (a) When and how to withdraw subjects from the trial/investigational product treatment.
 - (b) The type and timing of the data to be collected for withdrawn subjects.
 - (c) Whether and how subjects are to be replaced.
 - (d) The follow-up for subjects withdrawn from investigational product treatment/trial treatment.

6 TREATMENT OF SUBJECTS

- 6.1 The treatment(s) to be administered, including the name(s) of all the product(s), the dose(s), the dosing schedule(s), the route/mode(s) of administration, and the treatment period(s), including the follow-up period(s) for subjects for each investigational product treatment/trial treatment group/arm of the trial.
- 6.2 Medication(s)/treatment(s) permitted (including rescue medication) and not permitted before and/or during the trial.
- 6.3 Procedures for monitoring subject compliance.

(continued)

3.3

Example of Table of Contents (*continued*)**7 ASSESSMENT OF EFFICACY**

- 7.1 Specification of the efficacy parameters.
- 7.2 Methods and timing for assessing, recording, and analyzing efficacy parameters.

8 ASSESSMENT OF SAFETY

- 8.1 Specification of safety parameters.
- 8.2 The methods and timing for assessing, recording, and analyzing safety parameters.
- 8.3 Procedures for eliciting reports of and for recording and reporting adverse event and intercurrent illnesses.
- 8.4 The type and duration of the follow-up of subjects after adverse events.

9 STATISTICS

- 9.1 A description of the statistical methods to be employed, including timing of any planned interim analysis(es).
- 9.2 The number of subjects planned to be enrolled. In multicenter trials, the number of enrolled subjects projected for each trial site should be specified.
- 9.3 The level of significance to be used.
- 9.4 Criteria for the termination of the trial.
- 9.5 Procedure for accounting for missing, unused, and spurious data.
- 9.6 Procedures for reporting any deviation(s) from the original statistical plan (any deviation(s) from the original statistical plan should be described and justified in the protocol and/or in the final report, as appropriate).
- 9.7 The selection of subjects to be included in the analyses (e.g., all randomized subjects, all dosed subjects, all eligible subjects, evaluate-able subjects).

10 DIRECT ACCESS TO SOURCE DATA/DOCUMENTS

The sponsor should ensure that it is specified in the protocol or other written agreement that the investigator(s)/ institution(s) will permit trial-related monitoring, audits, IRB/IEC review, and regulatory inspection(s) by providing direct access to source data/documents.

<p>From <i>Guidance for Industry: E6 Good Clinical Practice: Consolidated Guidance</i>, U.S. Food and Drug Administration, 1996. Retrieved August 4, 2009, from http://www.fda.gov/downloads/RegulatoryInformation/Guidances/UCM129515.pdf.</p>

that is used in therapeutic trials as a substitute for a clinically meaningful end point that is a direct measure of how a patient feels, functions or survives and is expected to predict the effect of therapy” (Food and Drug Administration, 1992). In order to become a qualified surrogate, a marker must demonstrate a strong association with a clinical outcome in epidemiologic studies. Then it is evaluated as a possible surrogate in a treatment efficacy trial. It must not only correlate with the clinical end point but be predictive of the clinical end point in the presence of intervention.

It is important to note that in order to try accelerating drug development process, the FDA has proposed an accelerated approval rule to make new drug products available for the treatment of life-threatening diseases for which no adequate treatment exists before clinical outcomes are shown.

Surrogate outcome measures can be directly related to patient survival. For example, instead of waiting to learn whether a drug can extend cancer patients’ lives, the FDA might approve a drug based on evidence that

the drug shrinks tumors at a reasonable rate, because the evidence would be considered likely to predict a real clinical benefit, that is, longer life (U.S. Food and Drug Administration, 2007). The use of a surrogate marker could save a drug company valuable time in the drug approval process. However, for several reasons that will be described below, the drug company would most likely need to conduct phase IV studies to confirm that the predicted clinical outcome is indeed observed (i.e., the drug effect on tumor shrinkage actually does predict patients’ survival) after it is already approved.

Another kind of surrogate marker is utilized for diagnosis and prognosis, as in studies that use surrogate end points of disease risk (risk of developing a disease). The following are examples of surrogate end points of disease risk that have been accepted by the National Institutes of Health and/or the FDA’s Center for Drug Evaluation and Research: (1) serum low-density lipoprotein cholesterol concentration and blood pressure for cardiovascular disease, (2) bone mineral density for osteoporosis, (3) adenomatous colon polyps for colon

cancer, and (4) elevated hemoglobin A1c for diabetes (U.S. Food and Drug Administration, 2009).

Biomarker End Points

Surrogate markers are a subgroup of biomarkers that are qualified to substitute for outcome end points. The Biomarkers Definitions Working Group (2001) defines biomarkers as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.”

Biomarkers have a key role in early-phase studies in which the new drug is tested in healthy volunteers. At this early stage of drug development, the main focus of investigation is evaluating the safety, tolerability, and pharmacokinetics of the new compound. Since the drug is administered to healthy volunteers, the true effect of the drug on the disease cannot be determined. Therefore, many early-phase clinical trials test the drug effect on biomarkers.

A biomarker is usually considered a physiologic substance that can be measured in an objective manner. The investigator administers the drug to small groups of healthy volunteers or patients for a short period of time. Changes observed to the biomarker's level or activity following administration of the drug may indicate that the tested drug will have a significant/measurable effect on the disease state, symptoms, or even the patient's survival when given to a patient for longer duration. An example of a biomarker is the observed changes in the active frequencies of an electroencephalogram (EEG) recorded following administration of compounds developed for sleep or schizophrenia. Changes observed in the EEG may indicate that the compound is pharmacologically active in the brain but do not provide direct evidence of the desired clinical outcome (sleep induction or antipsychotic effect).

Of special interest are genetic biomarkers (a gene or a cluster of genes), which are being used more frequently for screening, diagnosis, decisions for treatment, and evaluation of patient response. The FDA has published a guidance for industry for this type of biomarker (U.S. Food and Drug Administration, 2008). This type of marker is generally not specific to efficacy (although it may predict if a therapeutic approach may be successful) and can provide insights about safety and pharmacokinetics. In most cases, genetic biomarkers are measured as exploratory end points and the results are collected from several studies. The “endophenotype” is an interesting type of genetic biomarker that was recently utilized for psychiatric research. For exam-

ple, distinct genes were identified that may be related to schizophrenia and are also linked to auditory stimulation. This information could therefore be employed when screening for schizophrenia by use of an auditory of an auditory test (Gottesman & Gould, 2003).

Table 3.4 provides common definitions of efficacy end points and their acceptance for regulatory purposes and some examples.

Advantages and Disadvantages of Biomarkers and Surrogate Markers

As mentioned earlier, the ability of biomarker level/activity changes to predict real clinical outcomes has not been confirmed. Some surrogate markers have been validated and can thus be used to predict clinical outcomes. The process of validation involves inducing a change in the marker and following the level of change in the outcomes. It is only after a direct relationship between a change in the marker and change in outcome is established that a marker is accepted as a surrogate. The surrogate marker may then be later utilized in place of a clinical outcome study. For instance, low-density lipoprotein cholesterol (LDLc) is a biomarker that is utilized as a surrogate for changes in cardiovascular outcomes. Pivotal controlled studies that demonstrate reductions in LDLc are accepted by several regulatory agencies as evidence of improvement in cardiovascular outcomes and negate the need for outcome studies.

Biomarkers, on the other hand, are exploratory measures that have been shown to be reproducible. In many cases, however, investigators and sponsors use them for more than just scientific evidence of pharmacologic activity and extrapolate changes in these markers as evidence of other potential benefits that have not been proved. Thus, relying on biomarkers in this manner may in some cases be risky.

It should be noted that there have been cases in which accepted surrogate end points were later proved to be unreliable predictors of clinical outcomes (Cardiac Arrhythmia Suppression Trial Investigators, 1989; Connolly, 2006). Since the connection between the surrogate marker and a change in the clinical outcome was based on assumption, the assumptions were eventually discredited once outcomes were rigorously tested.

Nevertheless, the means to obtain an early quantifiable read is still being pursued. Even though they are remotely related to disease outcome, biomarkers are frequently used for internal decision making in early drug development process. In some cases, in order to accel-

3.4

Efficacy End Point: Definitions, Use for Registration Purposes

END POINT	DEFINITION	ACCEPTANCE FOR REGISTRATION AND CLINICAL PRACTICE
Clinical outcome (clinical end point)	A characteristic or variable that reflects how a patient feels, functions, or survives. Clinical end points are distinct measurements or analyses of disease characteristics observed in a study or a clinical trial that reflect the effect of a therapeutic intervention. Clinical end points are the most credible characteristics used in the assessment of the benefits and risks of a therapeutic intervention in randomized clinical trials.	<ul style="list-style-type: none"> –The most credible for registration purposes –In clinical practice
Surrogate end point	A biomarker that is intended to substitute for a clinical end point. A surrogate end point is expected to predict clinical benefit (or harm or lack of benefit or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence. To achieve surrogate end point status, a biomarker needs to be qualified by demonstrating that a change in the biomarker will be reflected by a change in outcome.	<ul style="list-style-type: none"> –May substitute for clinical outcome data for registration purposes –Post-registration outcome trials are required –Often extended to clinical practice
Biomarker (biological marker)	A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.	<ul style="list-style-type: none"> –Serve for internal decision making and cannot substitute for an outcome study –Exploratory in nature and not common in clinical practice
Genomic biomarker (a subcategory of biomarkers)	A measurable DNA and/or RNA characteristic that is an indicator of normal biologic processes, pathogenic processes, and/or response to therapeutic or other interventions.	<ul style="list-style-type: none"> –Exploratory in nature –In some cases in clinical practice

erate the development of a compound, pharmaceutical companies use the changes observed in the biomarker levels/activity in healthy volunteers following treatment with the compound for decision making. In more extreme scenarios, these data are used to declare that a “proof of concept” was obtained (i.e., confirmation of pharmacologic efficacy). This tends to permit a risky leap directly into later phases of development, where the drug is tested in a large number of patients. On the

other hand, failure to show changes in biomarker level/activity in healthy subjects can result in a decision to discontinue a development program.

Safety End Points

Another kind of effect that is measured in both patient and healthy volunteer studies is the undesired effect, or the adverse event (also known as side ef-

fects). An adverse event (AE) is any undesired change in the subject's health while he or she is participating in the clinical trial—during the drug treatment period and within a pre-specified follow-up period. Most define an AE as any untoward medical occurrence in a patient or clinical investigation subject, which is usually temporally associated with the use of the product, regardless of whether or not it is considered to be related to the product. Therefore, an AE can be any unfavorable and unintended sign (including an abnormal laboratory finding), symptom, or disease (new or exacerbated).

Every drug treatment has some level of adverse events. However, for some drugs, AEs appear only if very large doses are taken (i.e., an overdose), while for other drugs, AEs may start to appear below the recommended clinical dose. The severity of adverse events can range from minor (e.g., slight skin flushing) to moderate to severe (e.g., illness requiring hospitalization up to death). Studies in animals (pre-clinical models) may provide some insight into the potential for as well as the nature of the adverse events that may appear in human studies. However, animals may not be the best predictor or model; therefore, in early phases of research, safety monitoring encompasses a very broad range of parameters until some level of risk is discharged. While the predictive nature of pre-clinical studies cannot be fully understood until the treatment is used in humans, animal studies are still commonly used simply due to lack of better models that can reliably reduce risk to humans.

The relationship between the adverse events and the disease may be obvious, as in cases of hallucinations following new therapy for insomnia or dizziness (due to low blood pressure) with new blood pressure medications. Others AEs, such as dry mouth following a new therapy for insomnia, may not be easily tied to the disease. AEs are categorized by their severity (mild, moderate, or severe), frequency of occurrence, and duration. Since most studies are conducted as double blind, the physician does not know what treatment was given to the patient. Therefore AEs are also categorized as treatment related, possibly treatment related, or not treatment related in order to establish causality or relationship to the treatment.

All AEs observed during clinical trials must be recorded. If an AE fits the criteria to be classified as serious, it must be reported within a specific time frame to the proper authorities (including but not limited to regulatory agencies, ethics committees/institutional review boards, safety monitoring boards, and the sponsor company). Records of minor AEs are documented and

sent on a regular basis, most often annually, to the regulatory authorities.

Serious adverse event reports are distributed to everyone involved in a study as a means to inform investigators and ensure patient safety. Serious adverse event reports outline the event, the opinion of the local investigator, and the opinion of the sponsor regarding the seriousness of the event in regards to the overall AE profile of the compound. This process allows the sponsor and all the investigators to review data while the study is still ongoing and flag potential problems with the study treatment.

Pharmacokinetic End Points

Pharmacokinetic end points are commonly monitored in phase I and phase II clinical trials. They involve the measurement of drug concentrations in the blood or plasma and are used to characterize the disposition/parameters about the drug in the body (metabolism, distribution, availability, etc). The drug concentration, or *exposure*, is related in many cases to the desired effect or to the AEs. One reason for monitoring the concentrations in clinical trials is to ensure that the drug exposure does not exceed a level that was determined in animal toxicity studies to be potentially toxic or harmful. The exposure level that researches stipulate as the cutoff is commonly called the no observed adverse event level and is presumed to be a threshold for safety in humans as well.

Depending on the trial design and the subject population, the pharmacokinetics of a drug may vary significantly. Thus it is evaluated in many cases: following single-dose and repeat-dose administration, with and without food, in different age and gender groups, and in specific patient populations, such as those with hepatic (liver) or kidney insufficiency. Since co-administration of the tested drug with other drugs may alter the pharmacokinetics of either drug, changes in the drug's pharmacokinetics are also evaluated in drug-drug interaction studies.

STATISTICAL CONSIDERATIONS IN CLINICAL TRIALS

Some common questions in clinical trial that need statistical support are:

What is valued as a measurement of the desired effect?
What study design will best help me to answer my questions?

How many subjects will I need?

Is the observed effect significant (that is, when compared to the placebo or active control)?

In clinical trials, just as in any other scientific experiment, statistical considerations have an essential role in the design, data monitoring, analyses, and reporting of the study. It is important for any investigator who does not have a mathematical/statistical background become familiar with the fundamentals of statistics. The authors of this chapter assume that readers have encountered the basic principles of statistics. While some principles will be described, the intent of this section is not to teach readers statistics but to highlight some statistical considerations relevant for clinical trials. Familiarity with these principles facilitates improved collaboration with the study statistician, resulting in better study designs and more informative results. Readers interested in widening their statistical knowledge are encouraged to read Chow and Liu's *Design and Analysis of Clinical Trials* (2004) and Moyé's *Statistical Monitoring of Clinical Trials: Fundamentals for Investigators* (2006).

Statistical Versus Clinical Significance

Ultimately, statistical analyses provide the investigator with a definite answer as to whether the effect observed in the test group is significantly different from that observed in the placebo or active control group. However, it should be emphasized that statistical significance does not always relate to the clinical importance of the treatment effect. Let's take an example of a new compound being investigated as a new therapy to decrease plasma levels of the LDLc.

The statistical analysis may find that the investigated new treatment produced significantly lower levels of LDLc than the placebo and active control treatments (12% and 4%, respectively). However, a commonly agreed-upon level of clinical significance for LDLc reduction treatments is 15% or greater. (Please note that any reduction in LDLc is considered good. However, to develop a new product to lower LDLc, a magnitude of 15% or greater is thought to add significant benefit to counter risks of long-term administration of the compound.) Thus, while statistical significance may be observed, in order to show clinical significance, a different benchmark may have to be met.

Furthermore, the minimal difference observed between the new treatment and the standard care

therapy (active control) will not convince any treating physician to replace the current therapy of his or her patient. While knowledge of and experience with the standard care therapy has accumulated, there are many uncertainties regarding the AEs of the new treatment.

The clinical significance is also related to the severity of the disease and availability of other drug treatments. While we do not automatically accept 12% in LDLc reduction compared to the placebo as substantial to warrant manufacturing and marketing of a new product for elevated cholesterol, similar magnitudes of change observed for a new drug tested for a rare form of cancer with no available treatment may be considered clinically relevant.

Sample-Based Research

When a researcher conducts a clinical trial with a new treatment for schizophrenia, he recruits 300 patients for the study. While he is clearly interested in learning about the effect in his 300 patients, the real intention of the study is to take the finding and apply it to the entire patient population (~24 million worldwide, according to the World Health Organization). While studying the new treatment in the entire population is impossible, the researcher may claim that his results apply to the entire population. Trying to extrapolate conclusions from a small population on a large population always introduces uncertainties. There is no guarantee that any chosen sample is a perfect representative of the entire population. However, following sound statistical principles makes it more likely that the results obtained from the small sample closely represent the results of the population from which the sample was drawn.

Hypothesis Testing

When comparing the new treatment with the placebo treatment, we may be facing two kinds of rival hypotheses. According to the null hypothesis (H_0), the basic statistical assumption is that the new treatment is not different from the control (i.e., they are the same). Since we are dealing with living entities, the results for the different treatments will not be identical but should be similar. Therefore, any observed difference between the treatments is considered to be by chance if the null hypothesis is true. Obviously, the expectation of the investigator is that the observed results will support rejection of the null hypothesis and acceptance of the alternative

hypothesis (H_A), which shows that the observed difference is genuine.

When one is trying to decide if the observed effect is truly different from the placebo effect, one simple approach is to compare the statistical means and to determine, prior to the beginning of the study, an acceptable value as a cutoff for the effect. This method is referred as a point estimate, where the effect ratio (drug: placebo) is predetermined. If the calculated value of the ratio is larger than the predetermined value (e.g., larger than 1.25), the effect of the test drug may be considered superior to that of the placebo treatment. This type of estimation approach is very easy to interpret. However, as will be described below, the estimation approach does not provide the maximal information from the comparison and therefore, in most cases, is not acceptable for comparison of drug effects.

If we are conducting a clinical trial with only a sampling of the population, we would like to know the probability that conducting a similar trial will provide the same answer. (Probability is the numerical measure of the likelihood that an event will occur, and its value ranges from 0 to 1.) The normal distribution is the most important probability distribution for experimental analysis. It has a bell-shaped curve and is defined by the mean and the standard deviation. Figure 3.1 illustrates a hypothetical case of a normal distribution: randomly measuring the height of 1,000 adult males (25–65 years of age) may produce an approximate normal distribution, with the average height being measured most frequently (left panel). When these results are transformed to probability (z score, right panel), the area under the distribution curve is equal to 1 (100%). Let's assume that these 1,000 subjects are the

real population. Now, we randomly measure the average height of groups of 20 subjects. Each small group (sample) will have its own average. A 95% confidence interval means that 95% of the time, the average of a sample group will lie within two standard deviations of the mean of the real population. Since the distribution curve is symmetrical, there is a 2.5% chance for a sample average to fall in each far end (tail) of the curve ($2.5 + 2.5 = 5\%$, thus accounting for the whole 100%). Similarly, three standard deviations will describe 99.7% of the sample means, with 0.15% falling into each tail (Moore, 1995).

The principles of probability, normal distribution and confidence interval apply when the effect of new drug is being tested in a clinical trial. According to the null hypothesis (H_0), the distribution of the effect results for the tested drug (our sample) and the control treatment (our real population) should be similar. The probability that the observed effect will occur if the null hypothesis is true is calculated. If this p value is very small (typically < 0.05), then the result is statistically significant and the null hypothesis is rejected in favor of the alternative hypothesis.

Figure 3.2 compares the effects of two new investigational treatments (A and B) to the effect of placebo treatment. The mean effects of both treatments (A and B) are smaller than the mean effect of the placebo treatment. If a point estimate approach were to be taken, both treatments A and B may be considered different from the placebo. However, for treatment A, the mean still resides within the 95% confidence interval of the placebo. Thus treatment A is considered to be not different from the placebo (null hypothesis is accepted = no effect). For treatment B, the mean resides outside

Figure 3.1 Normal distribution and probability.

Note: The 95% confidence interval lies within two standard deviations from the mean.

Figure 3.2 Null hypothesis rejection and acceptance of the alternative hypothesis for cases where $p < 0.05$.

Real life \ Study results	The new therapy works	The new therapy doesn't work
Positive		Type I Error, (α), p value typically 5%
Not positive	Type II Error, (β) typically 20% sometimes 10%	 ($1-\beta$) Power typically 80% sometimes 90%

Figure 3.3 Hypothesis testing.

the 95% confidence interval of the placebo. Thus treatment B is considered to be significantly different from the placebo (null hypothesis is rejected = alternative hypothesis is accepted = true effect).

Errors in Hypothesis Testing

In any decision making there is the possibility that one will make mistakes. Incorrectly rejecting the null hypothesis is one possible error (type I error; α [alpha]); another is incorrectly accepting it (type II error; β [beta]). Since these two errors have different consequences, they are treated differently. As illustrated in Figure 3.3, one possibility is that we wrongly decide that the results of our clinical trial are positive, whereas in real life the new therapy doesn't work. A false-positive decision poses a potential risk to society—approval of a drug that does not

work. Therefore, willingness to accept such a decision is low and historically has been set at 5% for each study.

The other possibility is that, although in real life the new therapy is supposedly effective, the results of our clinical trial are negative (i.e., no difference between the treatments). A possible outcome of such a false-negative decision may be discontinuation of the development of an efficient compound. As devastating as it may be to the investigator and to the sponsor, such a decision does not pose a real risk to society, and therefore the willingness to accept such a decision is higher. The commonly accepted β value in clinical trials is 20% (or 80% power). However, in many clinical trials that are sponsored by pharmaceutical companies, a value of 10% is used (90% power).

Sample Size Estimation

When one is planning a clinical trial, it is very important to consider the number of subjects necessary to provide a reliable result that is both statistically and clinically relevant. Enrolling too many subjects is both ethically and financially undesirable. Enrolling too few subjects does not provide a reliable definitive answer and may result in a need for additional studies (at best) or cancelation of the program, resulting in the denial of a potentially good treatment to patients.

Sample size is based on both statistical tools and on pragmatic considerations. Recruiting a large number of subjects for the study from a specific sick patient population may require large amounts of time and financial resources. Thus, the preferred sample size is the minimal required number of subjects that is sufficient to provide a reliable result.

In order to estimate the sample size, the statistician uses a formula that uses the alpha (false-positive) value (typically 5%), the adequate power (widely accepted as 80%), and the standardized difference, which is constructed from the available knowledge about the known average effect following control or standard of care treatment ($\pm SD$) and the anticipated effect following the tested therapeutic treatment.

In general, the sample size is larger:

- When the differences between treatments are expected to be small (also when comparing the treatment to active control rather than placebo control).
- With higher powers (most likely more participants will be required for 90% power than for 80%).
- With lower significance levels (reducing the chances for false positive [α] from 5% to 1%).
- When measurements are highly variable.

Since sample size estimation is based on several assumptions, different scenarios may yield dramatically different estimates of the sample size. Different size estimates in turn have crucial impact on the study design and the required time and financial resources. While describing the calculation process of sample size is beyond the scope of this chapter, the following example illustrates the effect of several scenarios on the estimated sample size. A study is planned to test if a new treatment is better than the standard therapy. While the observed effect size with the standard therapy is 50%, the anticipated effect size of the new treatment is 60%. The estimated sample size required in order to detect a treatment effect with 80% power at a 5% level of statistical significance will be 778 subjects.

Now, if we only change our assumption about the anticipated effect of the new treatment to 65% (instead of 60%), the required sample size will drop to 341 subjects. On the other hand, if we increase the power of the study from 80% to 90%, the required sample size will increase to 1,040 subjects. These assumptions and the estimated required sample sizes are summarized in Table 3.5.

We have tried to describe, in the most conservative way, the importance of statistical support throughout the entire process of clinical trial. In almost all cases, the investigators conducting trials have the support of well-trained statistician. It is not the intention of this chapter to train investigators in statistical techniques; rather it is to introduce them to some fundamental principles that need to be considered during the design of a study and analysis of the results. Familiarity with both the basic principles and the lingo facilitates better collaboration between investigators and the study statisticians, ensuring the selection of the appropriate designs as well as producing the desired significant statistical and clinical result.

EVIDENCE-BASED MEDICINE, PSYCHOLOGY, AND BEHAVIORAL SCIENCES

The next portion of the chapter will outline the impact that clinical trials have on the clinical practice of medicine, psychology, and behavioral sciences. We will try to emphasize how well-planned clinical trials have an actual influence on policy changes, such as recommendations to treat patients with a specific treatment or therapy. At the same time, the uselessness of small-scale studies that are not controlled or randomized will be highlighted.

3.5

The Effect of Different Assumptions on the Desired Sample Size for a Theoretical Clinical Trial

	SCENARIO A	SCENARIO B	SCENARIO C
Observed effect with standard care therapy	50 %	50 %	50 %
Anticipated effect of the new treatment	60 %	65 %	60 %
Power	80 %	80 %	90 %
Alpha	5 %	5 %	5 %
Required total number of subjects	778	341	1040

The small size and limited scope of individual investigations rarely, on their own, influence treatment paradigms for a particular disease treatment strategy or the prescribing of a class of medications. However, the compilation and subsequent analysis of many literature-based sources via the power of meta-analyses, as utilized in an evidence-based approach, can profoundly influence the direction taken or strategies utilized in a therapeutic area.

Conducting controlled, randomized clinical trials and publishing the results are key elements of the practice of evidence-based medicine (EBM). The process of systematically evaluating the quality of available evidence relevant to the risk and benefit of a treatment is currently the gold standard in medical practice. The term *evidence-based medicine* has been evolving since the early 1990s and refers to the ideal that health care professionals make “conscientious, explicit and judicious use of current best evidence” (Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996) in their everyday practice when making decisions about the care of individual patients. Health care professionals should base their treatment decision upon the most scientifically valid medical literature.

In order to evaluate the strength or robustness of evidence, EBM categorizes different types of clinical evidence and ranks them according to their freedom from bias. Review of several well-controlled randomized clinical trials is usually accepted as providing strong medical evidence, whereas sporadic or anecdotal information is usually biased and not controlled and there-

fore only provides unsubstantiated or weak evidence of efficacy and safety.

An example of how EBM can influence the prescription medicine can be found in the psychiatric field. The FDA performed a meta-analysis of several hundred trials of a number of antidepressants. The results suggested that the antidepressants included in the analysis may increase the risk of suicide in persons younger than 25. Subsequently, the FDA required all antidepressants to carry a black box warning describing this potential.

Level of Evidence and Category of Recommendation

Organizations have recently tried to develop standards for improving the reporting of clinical trials. The intention of standards for reporting is to provide guidance on how to conduct trials and how to report them for publication. Inadequate reporting may provide overly optimistic estimates of treatment effects. The Consolidated Standards of Reporting Trials (CONSORT) statement was published in 1996, revised in 2001, and subsequently accepted by most medical journals (Altman et al., 2001; Moher, Schulz, Altman, & CONSORT GROUP, 2001a, 2001b; Stinson, McGrath, & Yamada, 2003). Currently, several metric systems are available for ranking evidence of the effectiveness of a treatment. The U.S. Preventive Service Task Force has suggested five levels of evidence ranking, of which randomized controlled clinical trials have the highest level of evidence (Table 3.6).

3.6

Suggested Level of Evidence as Defined by the U.S. Preventive Service Task Force

LEVEL	EVIDENCE
Level I	Evidence obtained from at least one properly designed randomized controlled trial.
Level II-1	Evidence obtained from well-designed controlled trials without randomization.
Level II-2	Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.
Level II-3	Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled trials might also be regarded as this type of evidence.
Level III	Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

The UK National Health Service has presented similar methods.

Once the quality of the studies has been evaluated, a recommendation about whether clinicians should discuss or apply the new treatment with their patients can be made. Table 3.7 presents the five grades of recommendations as defined by the U.S. Preventive Service Task Force (2002–2003), based on the quality of evidence and the balance of risk versus benefit.

Published Clinical Trial Results:
The Source of Evidence-Based Medicine

In general, there are two sources that publish the results of clinical trials: the study sponsor (mainly pharmaceutical companies developing drugs) and independent researchers. Until recent years, results of only a limited number of studies were published for various reasons, depending on the source and nature of the results; in many cases there appeared to be bias in favor of publication of positive results. Due to the burden of perform-

ing independent comparative studies, a limited number of such studies are being conducted; these are mainly supported by the government (such as the National Institutes of Health in the United States). As a result, objective EBM evaluations have been hard to achieve since they relied on a meta-analysis of the available published data.

In recent years, two FDA-led initiatives that should influence the quality and objectivity of EBM were put into place.

As a result of U.S. Public Law 110–85, Title VIII (the Food and Drug Administration Amendments Act of 2007), the majority of clinical trials conducted in patients in the United States or sponsored by a U.S.-based company are to be published in the ClinicalTrials.gov database and Web site. While the database originally contained useful information about studies, it did not require publication of the results of completed studies. Following the retraction of several drugs from the prescription market due to toxicity findings, the new law mandates the expansion of the ClinicalTrials.gov Web site for better tracking of the basic results of clinical trials. The main results summary must now be published less than 90 days after study completion. The immediate consequence of this law is that negative and inferior results have to be published in addition to any positive results. Thus more objective EBM investigations can now be conducted.

While in the United Kingdom comparative effectiveness studies are conducted by the private sector, a limited number of such studies have been conducted in the past in the United States. Due to the need for objective and transparent decision making in the comparison of treatment options, the 2009 economic stimulus bill allocated money to support this type of research. Such research will allow doctors, health insurance companies, and the government to select the best treatment options for patients.

Evidence-Based Practice in Psychology
and Behavioral Fields

Evaluating the quality of new treatments in psychology and behavioral fields and deriving recommendations for them may be somewhat more complicated than EBM can accommodate. First, psychological and behavioral clinical trials cover both interventions that employ substances and interventions that do not. While trials with substance interventions are expected to be performed according to the rigorous guidelines of the Food and Drug Administration or other regulatory agencies, in-

Categories of Recommendation by the U.S. Preventive Service Task Force

GRADE	DEFINITION	SUGGESTIONS FOR PRACTICE
A (Strongly recommended)	The USPSTF recommends the service. There is high certainty that the net benefit is substantial.	Offer or provide this service.
B (Recommended)	The USPSTF recommends the service. There is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial.	Offer or provide this service.
C (No recommendation)	The USPSTF recommends against routinely providing the service. There may be considerations that support providing the service to an individual patient. There is at least moderate certainty that the net benefit is small.	Offer or provide this service only if other considerations support the offering or providing the service in an individual patient.
D (Not recommended)	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.	Discourage the use of this service.
"I" statement (insufficient evidence to make a recommendation)	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.	Read the clinical considerations section of the USPSTF's recommendation statement. If the service is offered, patients should understand the uncertainty concerning the balance of benefits and harms.

interventions that do not use substances are not always required to employ these criteria. Several methods, including the use of two-group parallel designs and the blinding of patients as well as clinicians, are likely to be difficult for many clinical psychological trials. The use of placebo control groups remains a challenge for psychological interventions. Other differences arise from the patient's diagnosis and prognosis: a conventional substance treatment is intended to treat one disease or symptom (hypertension, for example), whereas psychological intervention is more often holistic and intended to treat an array of symptoms. While the focus of randomized clinical trials is the comparison of two time points (after treatment vs. before treatment), psychological

treatment is also concerned with knowing the course of change during treatment (Laurenceau, Hayes, & Feldman, 2007).

The American Psychological Association has developed a set of criteria for considering psychological treatments to be empirically supported or evidence based. The criteria published in 1995 involve demonstration of statistical significance either in clinical trials with randomized group designs or by a large series ($n \geq 9$) of single-case experiments (Chambless et al., 1995.)

In 2005 the American Psychological Association Presidential Task Force on Evidence-Based Practice defined evidence-based practice in psychology as "the integration of the best available research with clinical

expertise in the context of patient characteristics, culture, and preferences” (Levant, 2005). According to the task force recommendations (which were later adapted by the American Psychological Association), evidence-based practice in psychology should be applied to any kind of intervention, including assessment, diagnosis, prevention, treatment, psychotherapy, and consultation.

In addition, the statement suggests that health care providers “join together to ensure that the research available on psychological practice is both clinically relevant and internally valid. It is important not to assume that interventions that have not yet been studied in controlled trials are ineffective. However, widely used psychological practices as well as innovations developed in the field or laboratory should be rigorously evaluated and barriers to conducting this research should be identified and addressed” (Levant, 2005). It supports the notion that the treating psychologist makes the ultimate decision regarding a particular intervention or treatment plan “in collaboration with the patient, based on the best clinically relevant evidence, and with consideration for the probable costs, benefits, and available resources and options” (Levant, 2005).

Evidence-Based Practice: The Case of Nonpharmacological Treatments for Insomnia

The following example illustrates how evidence-based practices have been used to determine the effects of psychological and behavioral interventions in order to identify and recommend best-practice interventions to practitioners.

Insomnia is a highly prevalent sleep disorder that has been associated with poor job performance and quality of life, as well as an increased risk of comorbidities such as depression and chronic use of hypnotics. Insomnia can be a primary disorder or a secondary disorder, where the insomnia is a symptom of, or associated with, other medical or psychiatric illnesses. There are several treatment options available for insomnia, including psychological/behavioral interventions, pharmacologic medications, and complementary or alternative therapies (herbal/dietary supplements, etc.).

The recognition that psychological and behavioral factors play an important role in insomnia has led to an increased interest in therapies targeting these attributes. In 1999, a review summarized the evidence related to the efficacy of psychological and behavioral treatments for persistent insomnia.

A task force appointed by the American Academy of Sleep Medicine conducted a systematic review on treatment studies published between 1998 and 2004 in an effort to constructively evaluate current psychological/behavioral treatment approaches to insomnia (Morin, Bootzin, Buysse, Edinger, Espie, & Lichstein, 2006). Studies had to use one of the following designs to be included in the task force’s review: randomized controlled trial, a nonrandomized group, a clinical case series, or a single-subject experiment with a minimum of 10 subjects. Of 53 relevant publications, 16 studies were rejected and 37 studies were found to ($n = 2,246$ subjects/ patients) meet the inclusion criteria. Readers should note that 30% of the conducted clinical trials that were published in journals were not even evaluated because of their poor study design. The task force used the Sackett system (1993) to determine the evidence level of each study selected for evaluation (all of which were peer reviewed). This evidence ranking system (which is similar to the method described in Table 3.6) considers well-designed randomized clinical trials to provide the highest level of evidence, and non-randomized historic studies or case reports to provide the lowest levels of evidence. After evaluating the evidence level of every study, the task force integrated the information and was able to develop recommendations. These recommendations were later approved by the board of directors of the American Academy of Sleep Medicine and were published as guidelines (Morgenthaler et al., 2006) and are expected to have a beneficial impact on professional behavior and patient outcomes and, in some cases, on health care costs.

The guidelines state that psychological and behavioral interventions are effective and recommended in the treatment of chronic primary insomnia, secondary insomnia, insomnia in older adults, and insomnia among chronic hypnotic users. Six specific types of therapies were found to be effective and are recommended to be used as a single therapy in the treatment of chronic insomnia. However, the task force determined that there was insufficient evidence available to make recommendations for utilization of one therapy over another, or to recommend a single therapy versus a combination of psychological and behavioral interventions. The task force determined that there was insufficient evidence for three specific therapies to be considered an option as a single therapy. Task force recommendations are summarized in Table 3.8.

3.8

Summary of the Recommendations of the American Academy of Sleep Medicine Regarding Psychological and Behavioral Treatments for Insomnia

General recommendations

Psychological and behavioral interventions are effective and recommended in the treatment of:

- chronic primary insomnia
- secondary insomnia
- insomnia in older adults
- insomnia among chronic hypnotic users

Recommendations about specific therapies

Sufficient evidence

The following interventions were found effective and recommended as therapies for the treatment of chronic insomnia:

- Relaxation training
- Sleep restriction
- Cognitive behavior therapy, with or without relaxation therapy
- Multicomponent therapy (without cognitive therapy)
- Paradoxical intention recommendation is unchanged
- Biofeedback

Insufficient evidence

Evidence was not sufficient for the following interventions to be an option as a single therapy:

- Cognitive therapy
- Sleep hygiene education
- Imagery training

From "Practice Parameters for the Psychological and Behavioral Treatment of Insomnia: An Update. An American Academy of Sleep Medicine Report," by T. Morgenthaler et al., 2006. *Sleep*, 29(11), 1415–1419.

chology and behavioral sciences has been reviewed on a high level. When considering new studies, clinicians and practitioners should keep in mind that only studies providing credible evidence of effectiveness should be considered when choices need to be made about new treatments, therapies, and policies. When poorly designed studies are conducted, many efforts and resources are invested, with little overall impact on the therapeutic approach.

IMPLEMENTING AN EMPIRICALLY SUPPORTED PSYCHOTHERAPY PRACTICE

In this chapter we summarize findings from practice-focused research conducted over the past 14 years at a large university counseling center. The most formal phase of our research involved gathering, archiving, and examining outcomes and was prompted by our adoption in 1995 of the 45-item Outcome Questionnaire (OQ-45) as the counseling center's preferred tool for evaluating psychotherapy outcomes. Most of this research was conducted to help us better understand how our clients responded to the psychotherapy services we offered. Some early findings were surprising and prompted follow-up questions. Several of our find-

ings contradicted traditional training and assumptions, prompting changes that benefited clients and which we hope others will consider.

OUR FACILITY

The Counseling and Career Center (CCC) is located in the student union building at Brigham Young University (BYU), Provo, Utah. There are also BYU campuses in Rexburg, Idaho, and Laie, Hawaii. All three campuses are owned by the Church of Jesus Christ of Latter-day Saints but are administered separately. This chapter considers personal counseling and psychotherapy services provided by the CCC at BYU-Provo.

With an enrollment of approximately 32,000 students, BYU-Provo is the largest religiously affiliated

university in the United States, and the nation's second-largest private university. The CCC offers free services to full-time students, without session limits. CCC services include psychotherapy, academic support, academic major and career advising, and career placement services. Only psychotherapy services are reviewed in this chapter.

CLIENTS

Demographics

Our database includes the records of all 23,024 clients who have scheduled and attended therapy appointments since June 1996, when our most recent database was established. Gender is recorded for 22,983 of these clients, 13,943 (60.7%) of whom are women and 9,040 (39.3%) of whom are men. Birthdates are available for 22,918 of our clients; the average age at first appointments was 22.66 years ($SD = 4.31$). Our youngest and oldest clients were 15.0 and 67.2 years old on the day of their first appointment. Report of race and ethnicity is voluntary at BYU. Declarations were given by 22,010 (95.60%) of our clients: 149 (0.65%) identified themselves as Black, 262 (1.14%) as American Indian, 477 (2.07%) as Asian, 386 (1.68%) as Pacific Islander, 1,213 (5.27%) as Hispanic, and 19,328 (83.95%) as non-Hispanic White, and 195 (0.85%) identified themselves as "other." Marital status is known for 22,729 (98.7%) of our clients: 12,198 (53.0%) are single, 10,177 (44.2%) are married, 335 (1.5%) are divorced, and 19 (0.1%) are widowed.

Diagnoses

During the first session, therapists recorded 180 different diagnostic impressions from Axis I and Axis II of the fourth edition and the text revision of the fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (1994, 2000). Because the modal length of cases at the CCC is one session and median case length is four sessions, early diagnosis of clients is not emphasized.

Presenting Problems

In 1994 the CCC joined a 36-university study organized by the Research Consortium of Counseling and Psychological Services in Higher Education to examine distress among college counseling center student clients. The Research Consortium was begun by the

Association of University and College Counseling Center Directors, with headquarters at the Counseling and Mental Health Center at the University of Texas, Austin. Clients participating in the research completed the OQ-45, which the CCC had already adopted, and several surveys designed by the consortium. These surveys included an alphabetically organized 42-item presenting problem checklist (PPC; Draper, Jennings, & Barón, 2003), which our faculty found helpful and voted to adopt as part of the initial paperwork to be completed by all new clients.

The PPC asks respondents to rate the degree of distress they experience in 42 potential problem areas, including academic, drug and alcohol, emotional, familial, interpersonal, sexual, and life planning domains. The PPC includes an open-ended 43rd problem item labeled "Other," which respondents can rate and for which a duration rating can be given. Ratings and scoring of the distress ratings are as follows: none = 0; a little bit = 1; moderate = 2; quite a bit = 3; and extreme = 4. Respondents also indicate duration of any distress experienced; the ratings and scores are as follows: less than a week = 0; 1–4 weeks = 1; 1–6 months = 2; 6–12 months = 3; 1–3 years = 4; and more than 3 years = 5.

Examination of our archived PPCs revealed that nearly all CCC clients reported that multiple problems were causing distress. On average, BYU students seeking treatment report 16 problem areas creating at least "a little bit" of distress. The most frequently endorsed PPC items at the CCC are, in descending order: academics, school work, or grades; anxiety, fear, worries, or nervousness; depression; self-esteem or self-confidence; concentration, tied with procrastination or getting motivated; stress management, tied with uncertainty about life after college, and tied with perfectionism; and decisions about a career or major.

Factor analyses conducted with different data sets at the different universities at which the PPC was administered show that PPC factor structure differs by setting and gender, suggesting that different constellations of problems present together based on the culture, background, or gender of the client in question. Women seeking services at the CCC report more problems and rate them as causing more distress than do men.

Is Client Psychopathology Increasing or Decreasing?

In a widely cited article about university counseling, Gerald Stone and James Archer (1990) predicted that

during the 1990s, students seeking services at college and university counseling centers would come with more symptoms of greater severity. As part of her dissertation research, Karen Evans (2005) evaluated this prediction at BYU by examining the PPCs and initial OQ-45s completed by 14,603 individuals from fall 1994 through summer 2004.

Evans looked for escalating distress by collapsing data into three equally sized groups. This adjusted for annual fluctuations and differences in sample size caused by BYU's increased enrollment and our growing caseload. The comparisons yielded somewhat contradictory patterns. Average number of PPC items endorsed and average total distress scores decreased over the period examined, $F_s(2, 14,600) > 13$, $ps < .001$. OQ-45 scores, however, increased over the same time period, $F(2, 11,203) = 24.68$, $p < .001$.

Evans was puzzled by the contradiction between the two scales. She suggested that the PPC provides a list of problems, a few related to emotional distress, such as anxiety and depression, balanced against many more that are developmental in character, for example, distress about grades, concerns about choosing a major and career, dating concerns, confusion about beliefs and values, reading and study skills problems, and trouble adjusting to the university. The OQ-45 consists of items that focus on emotional distress. It is possible that over the 10 years examined, developmental concerns grew somewhat less important among clients seeking treatment at the CCC while, as Stone and Archer (1990) predicted, the emotional distress that the OQ-45 is designed to measure increased.

THERAPISTS

Over the period of time researched, psychotherapy at the CCC was provided by 244 professionals and trainees. The professionals were 51 psychologists, 2 social workers, and a marriage and family therapist. The CCC's professional therapists have clinical faculty status, and some are assistant clinical professors, associate clinical professors, and clinical professors. Associate clinical professor and clinical professor are tenured ranks. Therapists describe themselves as having certification, training, or preferences for a wide array of therapeutic orientations; most also describe themselves as adopting an eclectic or integrative mixture of therapeutic techniques. Three psychiatrists and a psychiatric nurse-practitioner provided psychiatric consultation at the CCC, prescribing psychotropic medications.

Trainees were 18 postdoctoral residents, 41 interns, 160 doctoral psychology students, and 3 master's students in social work. Twelve of the residents, five of the interns and seven student therapists, eventually joined our faculty as professionals, providing clinical services in multiple roles as their training progressed. Trainees came from 34 accredited doctoral programs in professional psychology, including our own university's clinical and counseling psychology programs. All trainees were supervised onsite by our licensed professionals.

APPOINTMENTS AND SESSIONS

Use Patterns

During the period examined, 23,024 clients attended a total of 218,331 therapy sessions ($M = 9.48$; $Mdn = 4$; mode = 1) out of a total of 275,440 appointments ($M = 11.38$; $Mdn = 5$; mode = 1). Appointments consisted of 27,699 intakes (10.1% of appointments), 178,491 individual appointments (64.8%), 38,488 group sessions (13.97%), 15,928 couple's sessions (5.78%), 7,604 biofeedback appointments (2.76%), 4,543 psychiatric consultations (1.65%), 2,264 daytime crises (0.82%), and 423 evening crises (0.15%). Clients scheduled but failed to attend 57,109 (20.73%) of these 275,440 appointments. Missed appointments were divided among 23,960 no-shows (8.7% of appointments), 15,713 appointments rescheduled by clients (5.7%), 11,048 cancellations (4.01%), and 9,343 appointments rescheduled or missed by therapists (3.39%).

The Shape of the Caseload

The distribution of case lengths is distinctly non-normal. Figure 4.1 presents a histogram depicting the distribution of psychotherapy case lengths, showing the number of cases at each case length and the percentage of all cases represented at each case length. A distinct, sharply positive skew is evident in the distribution.

The distribution of our cases in Figure 4.1 shows that the notion of an average case or average client is not empirically supportable. The average case length, 9.48 sessions per client, provides a meaningful gauge of overall session use by clients, but this average does not provide useful information about any central tendency for case length. The next most commonly used indicator of central tendency, the median, which is four sessions among our clients, reveals the middle of the distribution of cases, showing that 50% of cases ended by the

Figure 4.1 Number of cases and percent of caseload ($N = 23,024$ cases) at each case length.

fourth session and that 50% ended thereafter. The extreme differences between the two ends of the distribution, however, reduce the usefulness of any index of central tendency. Our most common clients, the 4,934 clients who attended an intake or crisis session and did not return, account for 21.4% of our caseload. These one-session clients have very little in common with our 20 longest-treated clients, who account for 0.09% of our caseload and attended a total of 5,141 sessions. Though both groups of clients sought psychotherapy, the pattern of their treatments is so different as to make their cases qualitatively distinct from each another. Standard deviations have no meaning in distributions as asymmetric as the distributions of sessions and appointments for this sample.

Though the distribution of case lengths is remarkably skewed and asymmetrical, the distribution of case lengths is remarkably regular and predictable. The SPSS Regression Curve Estimation procedure was used to build a model of our caseload as a function of case length. The best-fitting model describes caseload as a

curvilinear function of case length. The model accounts for 97% of the variability in case lengths; $R^2 = .974$, $p < .001$. The best-fitting model depicts percentage of caseload taken up by a case of any given length as the reciprocal of the length of the case. This function is: percent of caseload = $(1/\text{case length} \times 23.7) - .2$. Thus, clients whose treatment lasts one session can be expected to account for 23.5% of our caseload $([1/1 \times 23.7] - .2 = 23.5)$. Clients whose treatment lasts five sessions can be expected to account for 4.54% of our caseload $([1/5 \times 23.7] - .2 = 4.54)$; clients whose treatments last 10 sessions can be expected to account for 2.15% of our caseload.

The regularity of the distribution also allows for accurate prediction of the likelihood that a client will return for the next appointment. Again, using a model derived from the curve estimation procedure ($R^2 = .904$, $p < .001$), the best-fitting model predicts the likelihood a client will return for a next session given the number of the current session: likelihood of return = $.821 + .0357 \times \text{natural log (current session number)}$. Thus, if today were

a client's first session, the likelihood that he or she will return for a second session would be .821 [$\ln(1) = 0$; $.821 + .0357 \times \ln(1) = .821$]; the probability of a third session, given a second session, would be .846 [$\ln(2) = .693$; $.821 + .0357 \times \ln(2) = .846$]; the probability of an eleventh session, given attendance at a tenth session, would be .903.

We were surprised by the skewed distribution of case lengths, by our finding that our most common cases last just one session, and by our finding that the distribution conforms so consistently to a simple mathematical function. When we searched the psychotherapy literature to see what others have written about case lengths, we were surprised to find how few mental health researchers have discussed such session-use patterns.

Horgan (1985) reported from the large National Medical Care Expenditure Survey that 22.2% of clients receiving mental health care make just one visit, while 25.3% make two to four visits, patterns very similar to the distribution of case lengths among our clients. Koss (1979) discussed and presented a table showing a sharply skewed distribution of 100 case lengths from the practices of seven private practice psychotherapists. It is almost certain that modal therapy length in this sample was one session, though she does not report it. Howard and colleagues (1989) conclude that therapists suffer from an illusion that their most common cases are long-term cases, when their most common cases are actually short-term cases. They present a table (p. 777) showing that the category of clients with the shortest case lengths, those attending one to four sessions, accounts for the largest percentage of cases, 24% of all clients treated. While skewed case lengths are an apparently common feature of psychotherapy treatment, it is an uncommon topic in outcome research.

Phillips (1985, 1987, 1991) analyzed session patterns in psychotherapy outcome research studies, psychotherapy sessions at a large university counseling center, relapse patterns at alcohol and drug treatment facilities, and compliance with doctors' orders at general medical practices and found that service utilization is remarkably regular in these settings. Attrition from psychotherapy, relapse during addiction treatment, and compliance with physician instructions for taking prescription medications all conform closely with decelerating curves, exponential decay curves, like the drop-off of case lengths in the distribution of case lengths at the CCC. Phillips suggested that understanding these patterns can strengthen our study of psychotherapy because the elegance and regularity of similar mathematical functions can be used to summarize, un-

derstand, and compare distributions of treatment usage in different settings.

Phillips's prediction, borne out in our data, makes his analyses compelling. Phillips made follow-up contacts with counseling clients who terminated from therapy after one to four sessions. Because 85%–90% expressed satisfaction with the treatment they had received, he suggested that these terminations from sessions 1 through 4 should be called attrition, not dropout. He further suggested that these patterns are likely best attributed to features of therapy delivery systems rather than to different kinds of therapy. His suggestions have largely been ignored by psychotherapy researchers.

Phillips (1985) suggested that given the rapid attrition evident in patterns like the pattern found in our caseload, clinics should focus on "rapid response" (p. 40) during early sessions. We concur and attempted to treat clients accordingly. Several related implications follow from the regular, steep, decay pattern.

- (1) Approximately 20% of our cases end at the first session. An intake screening that attempts to match clients with therapists wastes our most common client's only session. After examining the effects of intake screening, we abandoned classic intake sessions, as we explain below.
- (2) Spending early sessions taking a history or formulating a diagnosis similarly wastes treatment sessions for a majority of clients. A three-session diagnostic workup would fail to treat 43.2% of our clients. Diagnostic workups seem appropriate when clients are not on track for a positive outcome (we explain this further below) and after 10 or more sessions.
- (3) The rapid attrition in our caseload raises doubts about application of empirically supported therapies. Empirically supported therapies are often guided by manuals specifying the duration of interventions, which usually extend beyond the 75th percentile of our case lengths. On what basis do we decide which elements of an empirically supported therapy to deliver at early sessions?
- (4) Because short cases predominate in our caseload, we have focused on empirically validating interventions delivered at any session in any case, as we explain below.

Outcome as Measured with the OQ-45

Our faculty voted to adopt the 45-item Outcome Questionnaire (Lambert et al., 2004) as the CCC's standard outcome measure because it can be completed in about

five minutes and because it has excellent psychometric qualities, including excellent internal and test-retest reliability, and norms from community samples, from community mental health centers, from psychiatric inpatient facilities, from nonclient student samples at several universities, and from clients at several university counseling centers, including the CCC. The OQ-45 is strongly correlated with several other scales used widely in outcome research and has been used in outcome research at health maintenance and employee assistance facilities, independent mental health practices, training clinics, community mental health centers, psychiatric wards in general hospitals, a state psychiatric hospital, and several university counseling centers.

Clients complete the OQ-45 by estimating occurrence of 45 symptoms, emotional states, and situations during the previous week. Estimates for 36 problem items (e.g., item 2, "I tire quickly") are scored as never = 0; rarely = 1; sometimes = 2; frequently = 3; and almost always = 4. Estimates for the 9 positively worded items (e.g., item 1, "I get along well with others") are reverse scored as never = 4; rarely = 3; sometimes = 2; frequently = 1; and almost always = 0. Greater distress, symptoms, interpersonal problems, and social role dysfunction and fewer positive experiences, emotions, and relationships and adaptive social experiences yield higher scores.

At the time this chapter was written, OQ-45s had been completed by 19,981 clients, 86.78% of the 23,024 clients in this sample prior to 143,019 (65.5%) of their 218,331 sessions. Two or more OQ-45s were completed by 15,368 (60.9%) of the 25,255 clients. Average initial and final scores are $M_{\text{initial}} = 68.62$ ($SD = 23.11$), $M_{\text{final}} = 59.00$ ($SD = 23.98$). This 9.62-point average decline is statistically significant, $F(1, 15,367) = 3,103.1$, $p < .001$. Initial and final OQ-45 scores are highly correlated, $r(15,368) = .59$, $p < .001$.

The OQ-45 manual (Lambert et al., 2004) provides the psychometric information necessary for judging the clinical significance (Jacobson & Truax, 1991) of change. The statistical midpoint between clinical and nonclinical OQ-45 scores is 63.44 points. The reliable change index for any two OQ-45s is 14 points. The reliable change index and statistical midpoint can be used to divide our clients' change scores into 10 categories of clinical significance:

Casualties. 734 clients (4.8% of 15,368) began treatment with OQ-45 scores in the nonclinical range, at or below 63. Their scores then increased to a reliable degree, by 14 or more points, and finished in the clinical range, at or above 64.

Clinical cases that deteriorated. 593 clients (3.9%) began and ended treatment in the clinical range, and their OQ-45 scores increased by 14 or more points.

Nonclinical cases that deteriorated. 372 clients (2.4%) began and ended treatment in the nonclinical range but experienced reliable increases of 14 or more points in their scores.

Cases moving toward the clinical range, but not reliably so. The OQ-45 scores of 319 clients (2.1%) increased from the nonclinical range, below 64 points, to the clinical range, at or above 64 points, but their scores increased less than 14 points.

Clinical cases with no discernable change. 3,325 clients (21.6%) began and ended treatment with scores in the clinical range, and their scores changed less than 14 points.

Nonclinical cases with no discernable change. 502 clients (3.3%) began and ended treatment with scores in the nonclinical range, and their scores changed less than 14 points.

Cases moving toward the nonclinical range, but not reliably so. The OQ-45 scores of 3,488 clients (22.7%) moved from the clinical to the nonclinical range, but their scores decreased less than 14 points.

Improving nonclinical cases. 1,464 clients (9.5%) began and ended with OQ-45 scores in the nonclinical range and experienced reliable decreases of 14 or more points.

Improving clinical cases. 1,428 clients (9.3%) began and ended treatment with scores in the clinical range but experienced reliable decreases of 14 or more points.

Recoveries. 3,143 clients (20.5%) began treatment with scores in the clinical range, at or above 64 points; experienced reliable decreases of 14 or more points in their scores; and ended with scores in the nonclinical range, at or below 63 points.

Outcome and Treatment Cost

Linear Relationships

Treatment costs, as evident in appointment use and session attendance, are meaningful primarily in relation to client distress and improvement. There was, however, surprisingly little association between appointment use or session attendance and client distress or improvement. Numbers of appointments scheduled and sessions attended were uncorrelated with improvement, measured as the difference between the initial and final OQ-45 scores, $rs(15,368) < .015$, $ps > .10$, two-tailed.

Distress, as evident in the initial OQ-45 score, predicted appointments made, appointments kept, and appointments missed. Clients with higher initial OQ-45 scores made and missed more appointments and attended more sessions than clients with lower initial OQ-45 scores, $.08 < r_s < .10$ ($df = 18,855$), $ps < .001$, two-tailed. Though statistically significant, these correlations are tiny, accounting for less than 2 percent of the variability in appointments and sessions, $R^2s < 0.02$. The high statistical significance of the correlations shows that case length is predictable from initial distress at much better than chance levels. The low magnitude of the correlations shows, however, that knowing an initial OQ-45 score yields a predicted case length with such large error margins that the prediction has little practical value.

Curvilinear Relationships

We next tested for curving relationships between session use and change, relationships that weight some case lengths more heavily than others. Using the SPSS Regression Curve Estimation procedure, we found four reliable relationships between case length and improvement; $F_s(3, 15365) > 2.84$, $ps < .04$. Improvement was reliably related to total sessions attended as logarithmic, inverse, cubic, and s-curve functions of the total number of sessions attended. The best-fitting of these relationships was an inverse model: $OQ-45_{\text{improvement}} = 11.36 - [7.14 * (1/\text{session number})]$. This model predicts that improvement will reach its maximum of 11.36 points as case length reaches its maximum. The inverse model regression solution is a strongly significant solution, $F(1,15367) = 90.65$, $p < .001$, but the relationship is quite weak, accounting for less than 1 percent of variation in improvement scores, $R^2 = .006$. The high reliability of the regression solution shows that it is quite dependably predictable that improvement will increase as the inverse of sessions attended. The low magnitude of the relationship ($R^2 = .006$) shows that the regression equation yields a prediction with very large error margins.

Figure 4.2 presents the scatter plot of OQ-45 change scores arranged by case length. The curve depicting improvement as an inverse function of case length is superimposed over the scatter plot. Note that there is a noticeable rise in the regression slope, representing improvement through approximately session 10. From session 11 on, however, the regression line shows little noticeable increase. In other words, the relationship between case length and improvement reaches its maximum at about 10 sessions.

Follow-Up

As part of his dissertation research, Granley (2001) contacted 105 former CCC clients who had attended 3 to 10 therapy sessions. He asked that they complete a follow-up OQ-45 and a questionnaire describing their reasons for leaving therapy. The most common explanation for leaving therapy, given by 47 of 105 former clients (44.76% of respondents), was satisfaction with improvement attained. The next most common explanation for leaving therapy, given by 35 former clients (33.3%), was dissatisfaction with unsuccessful treatment. Thirteen former clients (12.4%) reported that they were dissatisfied with therapy but nonetheless believed they had improved. Finally, 11 former clients (10.5%) reported that circumstances had prevented them from continuing with therapy.

Initial OQ-45 scores among clients in the four groups were, on average, statistically indistinguishable. Clients in all four groups had, on average, improved reliably. Degree of improvement was statistically equivalent in the four groups, including among the 35 clients who reported that they left treatment because they were dissatisfied because they believed they had not improved. Follow-up OQ-45s completed by the 35 former clients who were dissatisfied with their lack of improvement did not show continued improvement. Clients in the other three groups continued to improve; their follow-up OQ-45 scores were statistically equal to and lower than OQ-45 scores among clients who reported terminating because they were dissatisfied with their level of improvement.

Granley's results suggest that early attrition should not necessarily be called premature termination. Even when former clients expressed dissatisfaction with therapy, they may have improved. Granley's follow-up data did not provide us with information about our two most common case lengths, cases lasting one and two sessions. Because the change scores and recovery curve depicted in Figure 4.2 are based on OQ-45s gathered at the beginning of clients' last-measured treatment session, Figure 4.2 is derived from the penultimate OQ-45 scores needed to assess outcome. Our faculty have, therefore, voted to institute a program of regularly following up with CCC clients. Clients will be informed during their first sessions that the CCC follows up with clients and may contact them to ask about their satisfaction with services and about how they are doing. Our first goal is to assemble a sample of responses from former clients so that proportions of case lengths in the follow-up sample match proportions of case lengths in the CCC caseload (see Figure 4.1).

Figure 4.2 Predicted change as a function of the inverse of case length.

Dose Effect or Goldilocks Effect?

The psychotherapy dose-effect model (Howard, Kopta, Krause, & Orlinsky, 1986) proposes that psychotherapy sessions, like drug doses, cause improvement. Howard and colleagues described a negatively accelerating curvilinear relationship between sessions and percent of clients reaching recovery. One interpretation is that earlier doses deliver stronger effects, while later doses are less potent for creating change.

Baldwin, Berkelson, Atkins, Olsen, and Nielsen (2009) examined OQ-45 scores among CCC clients to determine whether recovery patterns were a better fit with the dose-effect model or with the good-enough level of improvement model proposed by Barkham and colleagues (2006). This model proposes that clients stay in treatment until they reach what they and their thera-

pists consider good-enough levels of improvement. Earlier, at the 52nd Annual Conference on Mental Health Statistics, Jeb Brown (2003) reported that he had detected patterns similar to the good-enough level pattern in psychotherapy outcomes in two large managed care databases. He called this the Goldilocks effect: just as Goldilocks chose to sit in Little Bear's chair, eat Little Bear's porridge, and sleep in Little Bear's bed because they were "just right," clients in the managed care samples that he examined stayed in therapy until they felt just right.

Baldwin and colleagues (2009) found that change in OQ-45s were a better fit with the Goldilocks or good-enough level pattern than with the dose-effect pattern. Shorter and longer cases all tended to recover, but shorter cases reached recovery more quickly, terminating with fewer sessions. Shorter cases recovered faster

than longer cases. The steepness of recovery curves, meaning the speed of recovery, changed reliably and systematically as a function of case length, with recovery curves growing more shallow with longer cases.

The magnitude of initial OQ-45 scores was inversely related to the recovery. Less distressed clients recover more quickly, with shorter cases. The cases of clients who began treatment with higher initial OQ-45 scores tended to be longer and improve more slowly. Demographic and diagnostic differences added nothing to the prediction. A simple conclusion that can be drawn from this rather complex research is that during naturalistic, day-to-day psychotherapy, outcome is more accurately understood as clients responding to treatment at their own best pace, rather than as the pace and duration of treatment driving clients to respond.

Keeping Clients on Track for Improvement

For his dissertation research, Art Finch (2000) developed actuarial models of client recovery patterns. His goal was to generate growth curves and associated algorithms describing when a client is on track for recovery, given the initial OQ-45 score, current OQ-45 score, and session number. The classification algorithms he developed yield a psychotherapy quality control tool that can provide therapists with early warnings about likelihood of therapeutic failure (Finch, Lambert, & Schaalje, 2001).

Empirically Supporting Psychotherapy

Clinical Versus Actuarial Prediction of Deterioration at the CCC

Early psychotherapy outcome research consistently revealed that 5%–10% of clients deteriorate (Bergin, 1971). Outcome researchers largely ignored deterioration in favor of validating privileged psychotherapies (Lambert, Whipple, Hawkins, Vermeersch, Nielsen, & Smart, 2003). Outcome measurement tools could have been used to guide clinical practice, though this seldom happens (Stricker, Troy, & Shueman, 2000). The modeling of successful and unsuccessful therapy would be comparable to the routine use of pediatric growth curves to identify deviations from normal growth in order to trigger early interventions. Similarly, reliable psychotherapy recovery curves (e.g., Finch et al., 2001; Lutz, Lambert, Harmon, Stulz, Tschitsaz, & Schürch, 2006) could be used to identify deviations from expected improvement, prompting assessment and intervention to ward off poor outcomes.

Because therapists may not be alert to treatment failure (see, e.g., Breslin, Sobell, Buchan, & Cunningham, 1997; Yalom & Lieberman, 1971), Corinne Hannan (2006) investigated CCC therapists' ability to predict deterioration in their clients (see also Hannan, Lambert, Harmon, Nielsen, Smart, Shimokawa, & Sutton, 2005). She compared CCC therapists' predictions about the likelihood that their clients would deteriorate with predictions derived from the Finch (2000) algorithms.

CCC therapists were aware of the purpose of her study and were quite familiar with the OQ-45. They were told that the deterioration base rate at the CCC was approximately 10%. CCC therapists were still unable to correctly identify 39 of the 40 clients from among the 550 clients included in the study who would eventually deteriorate. The Finch algorithms correctly identified 36 of the 40 clients who would eventually deteriorate. Providing therapists with the Finch actuarial predictions might have allowed them to prevent their clients from deteriorating.

Actuarial Early Warnings

Four randomized, controlled experiments (Harmon, Lambert, Smart, Hawkins, Nielsen, Slade, & Lutz, 2007; Lambert, Whipple, Smart, Vermeersch, Nielsen, & Hawkins, 2001; Lambert, Whipple, Vermeersch, Smart, Hawkins, Nielsen, & Goates, 2002; Whipple, Lambert, Vermeersch, Smart, Nielsen, & Hawkins, 2003) were conducted at the CCC to test the effects of providing therapists and clients with actuarial predictions. Most of these data were gathered during dissertations designed to build on the Finch dissertation research (Harmon, 2005; Slade, 2008; Whipple, 2002).

Therapist effects were controlled for by randomized assignment to treatment. Clients treated by clinical faculty, by resident psychologists, by interns, and by student therapists were assigned at random to either treatment or control conditions. The therapists of those assigned to the experimental treatment were informed of the outcome predicted for a client by the Finch algorithms. Predictions from the Finch algorithms were withheld from those assigned to the control condition. The Finch algorithms provided four predictions: clients could be (1) on track for recovery; (2) ahead of schedule for recovery, meaning reliably ahead of clients who were on track for recovery; (3) not on track, meaning reliably deviating from expected recovery trajectories and therefore less likely to recover; or (4) at risk, meaning not on track, but not in the not-on-track status.

The therapists of clients in the experimental condition were also provided with evolving sets of clinical

support tools, including suggestions for case management and assessment information about clients who are at risk and not on track. If clients were determined to be at risk or not on track, they might, depending of the version of the experiment, complete questionnaires about the therapeutic relationship, about recent stressful life events, about their social support resources, about their readiness for change, or about their levels of perfectionism. If a client was in the experimental condition, the client's therapist would, depending on the iteration of our evolving experiments, receive suggestions about case management and results from questionnaires completed by clients determined to be at risk or not on track. Therapists of clients in control conditions would not receive at-risk or not-on-track warnings and would not receive clinical support tools.

Informing therapists that clients were at risk or not on track yielded reliably better outcomes than withholding that information from therapists. Clients in the experimental condition had 25% better outcomes in the first experiment, and 35% better outcomes in the second and third experiments. When therapists of treatment group clients were informed of clients' at-risk or not-on-track status and were also provided with clinical support tool information, at-risk and not-on-track clients had 60% better outcomes than when therapists were not informed of clients' at-risk or not-on-track status and were not provided with clinical support tools.

Informing therapists about actuarial predictions also changed session use. When therapists were warned that their clients were at risk or not on track, their clients attended more sessions than at-risk and not-on-track clients whose therapists were not warned about clients' at-risk or not-on-track status. Two of the four experiments found that informing therapists that their clients were on track or ahead of schedule yielded reliably shorter therapies, though on-track and ahead-of-schedule clients were equally likely to improve whether or not their therapists were informed of their status. Providing therapists with predictions from the Finch algorithms helped them get extra treatment sessions to clients who needed them and may have helped them economize on session use when clients were on track for recovery.

One of the most important elements of these experiments is that clients in experimental and control conditions were treated by the same therapists. The benefits of providing actuarial predictions helped regardless of the therapist's experience level or his or her allegiance to a particular kind of therapy. The same therapists achieved better and worse results based on whether or not they received information about their clients. Re-

sults from these experiments established a new CCC goal of guiding therapy through empirically derived, systematic use of outcome information.

Results from these experiments were used to refine reporting methods and develop Web-based software that provides real-time administration, charting, and analysis of client scores. This system has been available for use by CCC therapists since 2005. Figure 4.3 presents a faux report like the reports generated by this software system for a 25-year-old client who was not on track when he completed the OQ-45 on August 14, 2007. Joe completed the OQ-45 on a handheld computer. His score was transmitted to a desktop computer and Internet server and a report like the report presented in Figure 4.3 was available for examination over a secure Internet connection as Joe walked from the reception area to the consulting room. The therapist and Joe reviewed and discussed the report during the session.

Note that Joe's scores fluctuated between predictions that he was not on track, at risk, and on track. Joe remained in therapy for 36 sessions after the session recorded here. Joe's therapy included weekly review of successive reports like that in Figure 4.3. His scores were on track by his 47th session and went into the recovered range at his 69th session.

Improving Clinical Support Tools

Russell Bailey (2008) completed the most recent intervention dissertation conducted at the CCC. Using item-response theory, he developed and validated a short questionnaire to replace the multiple questionnaires used in clinical support tools during previous experiments. This brief Assessment for Signal Clients (ASC) reduces assessment time, which is likely to improve acceptance of clinical support tool use, which may increase client compliance. The ASC is now administered on the same handheld computers used to administer OQ-45s. Results are scored immediately upon completion and transmitted to clinicians' computers, where they can also be read as clients walk to the consulting office.

Tiffany Washington, a clinical psychology student, is currently conducting dissertation research at the CCC on the administration of the ASC early in treatment, before empirical algorithms would usually generate warnings. She provides therapists with their clients' scores on a random basis. Her goal is to determine if early ASC reports facilitate better outcomes, including the reduction of deterioration rates evident among not-on-track clients.

Name: Joe Student	ID:	Alarm Status: Red
Session Date: 8/14/2007	Session: 38	Most Recent Score: 109
Clinician: Nielsen, Lars	Clinic: CCC	Initial Score: 102
Diagnosis: Unknown		Change From Initial: No Reliable Change
Algorithm: Empirical		Current Distress: High
Instrument: OQ®-45.2		

Most Recent Critical Item Status:		Subscales	Current Score	Outpt. Norm	Comm. Norm
8. Suicide - I have thoughts of ending m life.	Never	Symptom Distress:	69	49	25
11. Substance Abuse - After heavy drinking I need a drink the next morning to get going.	Never	Interpersonal Relations:	96	20	10
26. Substance Abuse - I feel annoyed by people who criticize my drinking.	Never	Social Role:	109	14	10
32. Substance Abuse - I have trouble at work/school because of drinking or drug use.	Never	Total:	109	83	45
44. Work Violence - I feel angry enough at work/school to do something I might regret	Rarely				

**Graph Label Legend:**

R = Red: Not On Track. High chance of negative outcome.
Y = Yellow: Not On Track. Some change of negative outcome.
G = Green: On Track. Making expected progress.
W = White: Functioning in normal range.

Feedback Message:

The patient is deviating from the expected response to treatment. They are not on track to realize substantial benefit from treatment. Chances are they may drop out of treatment prematurely or have a negative treatment outcome. Steps should be taken to carefully review this case and identify reasons for poor progress. It is recommended that you be alert to the possible need to improve the therapeutic alliance, reconsider the client's readiness for change and the need to renegotiate the therapeutic contract, intervene to strengthen social supports, or possibly alter your treatment plan by intensifying treatment, shifting intervention strategies, or decide upon a new course of action, such as referral for medication. Continuous monitoring of future progress is highly recommended.

Figure 4.3 Sample OQ analyst report.

Abandoning Intake Because of Intake Therapist Discontinuity Effects

As noted above, the skewed shape of the distribution of case lengths suggested that intake appointments might prevent our most typical clients from receiving treatment. A few years ago the following conversation took place during an intake session:

- Therapist: "How might we help you?"
 Client: "Uhm, this is an intake, right? So, I tell you about my problems and you decide who I should meet with, right?"
 Therapist: "Is there someone in particular you'd like to see?"
 Client: "No. I just don't want to get into it all now and then again with someone else. I've been in therapy before, and I just don't want to go over it any more than I have to."

The client's concern and our understanding of the skewed distribution of case lengths at the CCC prompted comparison of attendance, treatment utilization, and outcome patterns among the 6,341 clients who continued in treatment with their CCC intake therapists, with attendance, treatment utilization, and outcome patterns among 8,026 clients who entered treatment with a CCC therapist different from their CCC intake therapist (Nielsen et al., 2009). We called the pattern of entering treatment with a therapist different from the intake therapist "intake therapist discontinuity" (ITD).

ITD clients were about twice as likely as clients entering therapy with their intake therapists to terminate by missing the appointment after intake. Improvement among ITD clients appeared to be delayed by about two sessions, compared to clients who entered treatment with their intake therapists. Figure 4.4 shows average OQ-45 scores among CCC clients from intake through session 5. It is evident that ITD clients improved less at sessions 2 and, the first two sessions after intake, than clients continuing in therapy with their intake therapists, catching up at sessions 4 and 5. Though more likely to terminate by missing the session after intake, ITD clients made 2.26 more appointments, on average, than clients who entered treatment with their intake therapists. The extra appointments did not yield better outcomes for ITD clients.

These patterns suggest that ITD disrupted the earliest phase of psychotherapy, dissuading some clients

from returning after intake, and slowing improvement among ITD clients who did return after intake. This retarding of improvement lengthened the time it took for ITD clients to improve, compared to clients who began psychotherapy at their first meeting with a therapist, making treatment of ITD clients about 18% more expensive than treatment of clients entering treatment with their intake therapists.

Given these patterns and the predominance of short cases evident in Figure 4.1, our clinical faculty voted in late 2006 to abandon formal intake, with the dual goals of minimizing initial therapist discontinuity and completing as much treatment as possible with new clients by beginning therapeutic interventions as early as possible. As of January 2007, therapy at the CCC begins with initial sessions rather than with intake sessions. The goal of initial sessions is to retain new clients in treatment with their initial therapist. For the last two years, 2007 and 2008, 82% of clients entered treatment with the first therapist they met. Overall improvement as measured with OQ-45 scores is unchanged, but appointment and session use have decreased by approximately 10%. We have not identified increases in client transfers or untoward therapeutic events. Supervisors have not reported problems finding appropriate cases for their trainees.

Therapist Effects

Beginning with his dissertation research and continuing through two subsequent investigations, John Okiishi and his colleagues have examined the recovery curves at the CCC in order to understand different therapists' unique outcome patterns (Okiishi, 2000; Okiishi, Lambert, Eggett, Nielsen, Dayton, & Vermeersch, 2006; Okiishi, Lambert, Nielsen, & Ogles, 2003). Okiishi cites the exceptional outcomes of a therapist whom David Ricks (1974) called "supershrink" as impetus for this research interest. Supershrink's therapeutic skills in treating adolescent clients were sufficient that the boys he treated were doing quite well as adults.

In their most recent study of CCC therapists' outcomes, Okiishi and colleagues (2006) collected the OQ-45s of 6,499 clients seen by 71 different CCC therapists over a six-year period. When hierarchical linear modeling (Bryk & Raudenbush, 1992) was used to compare them, therapists' change rates differed significantly. Clients treated by the seven therapists with the best change rates improved at a rate about twice that of the CCC average rate. Conversely, clients treated by the seven therapists with the worst change rates improved at a rate of about half that of the CCC average rate. No reliable differences in change rates could be attributed

Figure 4.4 Average OQ-45 scores of clients who entered or anticipated entering therapy with therapists different from their intake therapists and those of clients who entered or anticipated entering therapy with their intake therapists.

to therapists' theoretical orientations, type of training, experience, or gender.

Clinical significance of change scores (Jacobson & Truax, 1991) was also examined. Twice as many clients treated by the seven therapists with the best change rates recovered to a clinically significant extent as those treated by the seven therapists with the worst change rates. Half as many clients treated by the top seven therapists deteriorated to a clinically significant extent as those of the seven therapists with the worst change rates.

Okiishi and colleagues provided CCC therapists with confidentially generated descriptions of their change rates. In order to render change rates confidential, an outsider replaced therapist and client identifiers with codes, blinding statistical analysts to therapists' identities. Therapists were provided with their code number,

which they then used to retrieve their individualized reports. Individualized reports provided them with their change trajectory and compared their trajectory with an aggregate change trajectory based on the trajectories of the 70 other CCC therapists. Each therapist was provided with the improvement and deterioration rates of his or her clients, categorized according to clinical significance criteria (Jacobson & Truax, 1991), and compared with general CCC improvement and deterioration rates. Clients were also provided with the average length of their cases compared with CCC average case lengths.

As part of a dissertation project conducted by David Dayton that is now underway, therapists have been interviewed about the impact of the data presented to them during the 2006 study. Most therapists reported that they wanted more specific information in order to better

understand their improvement and deterioration rates, particularly the identities of clients classified as deteriorated during treatment. Some therapists were enthusiastic about the study information, while others were dismissive or skeptical of the accuracy of the data. Some therapists expressed feelings of discouragement because their data did not look as “good” as they had expected. Because of Dayton’s preliminary findings, Okiishi and colleagues are trying to create more encouraging, useful ways to present information about therapist outcomes. Another round of feedback to CCC therapists is planned for 2009.

Couples Therapy

When married clients seek treatment for emotional disturbance, the question sometimes arises whether to treat them for their emotional disturbance in individual or couples therapy. Comparisons have failed to find superior outcomes when the psychological disorders of individuals are treated in individual or in couples therapy (Emanuels-Zuurveen & Emmelkamp, 1996; O’Leary & Beach, 1990). Research has also failed to examine the role of married clients’ initial distress in the therapeutic outcomes of individual and couples therapy.

Archival research was conducted at the CCC to examine the comparative effectiveness of individual and couples therapy for treatment of the individual emotional disturbance of married clients (Isakson, Hawkins, Harmon, Slade, Martinez, & Lambert, 2006). Of particular interest was how the initial disturbance of partners might relate to outcomes of couples therapy. Would outcome vary according to initially matching or mismatching levels of distress as measured with the OQ-45? Particularly, would outcomes vary when partners matched or did not match each other for clinical and nonclinical levels of initial distress? The statistical midpoint between OQ-45 scores in clinical and nonclinical standardization samples is 63.44 points. Scores of 64 and higher are in the range of clinically significant distress.

A sample of 190 married CCC clients who were treated in couples therapy was drawn from the CCC treatment archive. They were divided into four groups based on initial OQ-45 scores: both partners in 25 couples were in the clinical range, with initial OQ-45 scores greater than 63; both partners in 25 couples were in the nonclinical range (OQ-45 < 64); 24 couples were mismatched, with the husband in the clinical range and the wife in the nonclinical range; and 21 couples were mismatched, with the wife in the clinical range and the husband in the nonclinical range. Another 1,445 clients were selected from the CCC archive to provide an outcome benchmark.

Clients in couples therapy and in the benchmark sample whose initial OQ-45 scores were in the clinical range (OQ-45 > 63) improved to a reliable degree during treatment, t_s ($dfs > 148$) > 5.5, $ps < .001$, two-tailed. Clients in couples therapy and in the benchmark group whose initial OQ-45 scores were in the nonclinical range (OQ-45s < 64) did not improve to a reliable degree, $t_s < 1.5$. Change was statistically equal in the couples therapy and benchmark samples.

When both husbands and wives in couples therapy began in the clinical range, both improved, on average, $t_s(23) > 2.2$, $ps < .05$, two-tailed. When neither the husband nor wife in couples therapy began in the clinical range, wives improved to a reliable degree, $t(23) = 2.77$, $p < .05$, two-tailed, but husbands did not, $t(23) < 1$. Unlike benchmark clients, women who were not initially experiencing clinical levels of distress could still improve when treated in couples therapy. When a distressed man entered couples therapy with a wife who was not distressed, the man improved to a reliable degree during couples therapy, $t(22) = 4.71$, $p < .001$, two-tailed, but the wife did not, $t(22) < 1$. When a distressed woman entered couples therapy with a husband who was not distressed, neither wife nor husband improved to a reliable degree, $t_s(19) < 1.9$, $ps > .05$.

These patterns suggest that husbands and wives in couples therapy respond differently, depending both on their own and their spouses’ initial levels of distress. To further test for the moderating effects of initial distress, matching samples of 24 distressed married men and 21 distressed married women who had been treated in individual therapy were drawn from the therapy archive. They were selected so that their initial OQ-45 scores matched, respectively, the initial OQ-45s of the 24 distressed men who entered couples therapy with non-distressed wives and the OQ-45s of the 21 distressed women who entered couples therapy with non-distressed husbands.

Distressed men who entered couples therapy with non-distressed wives and the matching married men in individual therapy improved at levels that were statistically equal, $t(46) = 1.02$, $p > .3$. Distressed women who entered couples therapy with non-distressed husbands improved less than the matching married women treated with individual therapy, $t(40) = 2.14$, $p < .05$, two-tailed.

To summarize, when both partners in couples therapy were clinically distressed at the beginning of treatment, both spouses improved during couples therapy. When neither spouse was clinically distressed at the beginning of treatment, wives improved during couples

therapy. Distressed married men benefited equally from individual and couples therapy, regardless of how distressed the wives of the men in couples therapy were when the therapy began. However, distressed women entering couples therapy with husbands who were not distressed had poorer outcomes than distressed married women who were treated in individual therapy.

Couples therapy at the CCC appears to provide effective and efficient treatment for distressed married couples. When married couples who are not experiencing clinically significant distress enter couples therapy, wives do better, even though they were not significantly distressed when they entered therapy. Distressed husbands appear to do equally well in couples and individual therapy, regardless of whether their wives are distressed. Individual therapy may, however, be a more effective way to treat distressed married women if their husbands are not experiencing clinically significant distress.

Ethnic Minority Clients

The U.S. surgeon general's 2001 supplemental report, *Mental Health: Culture, Race, and Ethnicity*, suggested that mental health practices in the United States fail to meet the needs of ethnic minorities. Lambert, Smart, Campbell, Hawkins, Harmon, and Slade (2006) attempted to understand how well the CCC does at treating ethnic minority clients by comparing the OQ-45 scores of 476 ethnic minority clients who received treatment at the CCC with those of 476 White clients selected to match the 476 minority clients for gender, marital status, age, and initial OQ-45 score. The samples drawn from the therapy archive were 29 African Americans and 29 Whites matched for initial OQ-45, gender, marital status, and age; 118 Asian/Pacific Islanders and 118 matched Whites; 279 Latinos/Latinas and 279 matched Whites; and 50 Native American and 50 matched White clients.

All eight groups, the four ethnic groups and the four matched White cohorts, improved during treatment, $F(7, 944) = 4.98, p < .001$. OQ-45 scores in all eight groups improved to a statistically indistinguishable degree, $F(7, 944) < 1$. Group-by-group comparisons of the improvement experienced by each ethnic group and the improvement experienced by its matched White cohort were also unreliable. Improvement scores were statistically indistinguishable, $ts < 1.38, ps > .2$. Though differences between ethnic groups and matched White cohorts were not reliable, the OQ-45 scores of African American and Native American clients improved more than the scores of their matched White cohorts.

Psychotherapy and Grades

For her dissertation research Dianne Nielsen (2001) explored the relationship between psychotherapy at the CCC and academic performance at BYU. An archival sample of 3,789 CCC clients was compared to a matched sample of 3,789 nonclients; both clients and nonclients were students. Hierarchical linear modeling (Bryk & Raudenbush, 1992) was used to control for the relationship between BYU semester GPAs, high school GPA, standardized admission test scores, gender, and enrollment period. Clients had higher standardized admission test scores and high school grade GPAs than nonclients.

Hierarchical linear modeling analyses showed that client and nonclient semester GPAs were equal before clients began treatment at the CCC, and that clients' GPAs dropped during semesters when they received treatment, then recovered, reaching near nonclient levels during semesters after treatment. High school GPA and admissions test scores predicted semester GPAs, but they did not predict OQ-45 scores. University GPAs during the semester prior to treatment were weakly negative predictors of initial OQ-45 scores; that is, better GPAs predicted lower initial distress. OQ-45 improvement during treatment predicted better GPAs in subsequent semesters; that is, the more clients improved during treatment, the better they did during subsequent semesters.

Nielsen noted that her analyses were correlational, as it was not possible, nor would it have been ethical, to gather control samples of nonclient BYU students who were experiencing clinically significant distress, place them on a semester-long waiting list for therapy, then compare their grades with treated students. The positive predictive relationship between improvement and subsequently improved GPAs provides some evidence that successful treatment improves academic performance. Advances in causal modeling may allow for better analysis of causal relationships between academic readiness, past performance, emotional distress, improvement during treatment, and subsequent academic performance.

LIMITATIONS

CCC faculty have been productive in conducting research and have presented scholarly papers derived from CCC research at annual American Psychological Association, Association for Behavioral and Cognitive Therapy, American Group Psychotherapy Association,

and International Society for Psychotherapy Research conventions every year for the past 20 years. CCC research is, however, conducted with small budgets and within limited time frames. Interesting findings presented at conferences have sometimes languished for years without being published because of the time it takes to get papers published in refereed journals.

The most visible feature in CCC research, measurement of outcomes with the OQ-45, is limited by weaknesses in the OQ-45. The OQ-45 does not, for example, provide as much information about low-scoring clients. Some clients with low OQ-45 scores complain of and display significant distress during sessions. The CCC needs alternative tools for assessing clients' reasons for seeking treatment and for measuring client change. Adding new methods or tools at a busy counseling center is quite challenging, however. Because of the complexity inherent to obtaining agreement and cooperation about adding or changing the daily work of providing services to clients, adding or changing methods and tools is similar to slowing or turning a very large boat.

WHAT HAS HELPED THE RESEARCH

Professional Faculty Status

The CCC began as an amalgamation of BYU services, with staff and faculty coming from several departments and service sectors. Some came to the CCC with faculty status, some came as administrative staff, and some came with tenure. This created disparate salary, advancement, and rank expectations with no central governing criteria. Establishment of a uniform, professional tenure system to supplement the already well-understood professorial tenure system was proposed to the university administration by counseling center professionals in 1985. A broadened professional tenure system was adopted by the university in 1990. In addition to a clinical tenure track for CCC professionals, professional tenure tracks were established for librarians, coaches, and laboratory and teaching specialists.

The CCC then established a tenure and rank committee. Currently the 58-member CCC staff includes 31 full-time doctoral-level mental health professionals who are assistant clinical professors, associate clinical professors, and clinical professors. Four other mental health professionals have earned clinical faculty tenure at the associate clinical professor or clinical professor level through the CCC but serve outside the CCC. One of these faculty members left the CCC to serve as dean of students then left the deanship to serve as Student

Life vice president. The director of the university's accessibility center was hired independently to direct the center, but applied for and received tenure as an associate clinical professor.

Criteria for advancement focus first on therapeutic effectiveness and productivity but weigh combinations of administrative, teaching, program development, university citizenship, and scholarship activity. The development of tenure standards forced the CCC faculty to codify professional activities, including validating the effectiveness of psychotherapy.

New hires are scrutinized for their potential as practitioners, administrators, scholars, teachers, and researchers. Tenure protection brings obvious benefits to CCC faculty. Protection of tenure fosters frank discussion about validating services. Mentors are assigned to guide new faculty through candidacy for tenure at three years, and final review for tenure and advancement at six years. Expectations for scholarly work in support of tenure have been perhaps the most important stimulus for increasing faculty research activity.

Expansion of Professional Training

Planning for internships in professional psychology began in the CCC in the mid-1980s with designation of a training director and the establishment of a training committee. Annual hiring of three predoctoral psychology interns began in 1989. Accreditation by the American Psychological Association came in 1992. The three internships expanded to four in 1995.

Most new faculty hired since establishment of professional tenure have been new PhDs just finished with internships and doctoral dissertations, and still in need of postdoctoral supervision to meet state licensing requirements. Retirements and growth fueled by expanding university enrollment led to a frequent enough need for postdoctoral supervision that the CCC has run a de facto postdoctoral residency in psychology for most of the past 15 years.

After the CCC internship was accredited, BYU's department of counseling psychology and special education sought American Psychological Association accreditation for its counseling psychology program. Expanded supervised training settings were needed as the training program expanded. The department negotiated to have the CCC provide practicum training spots and for CCC faculty to participate in instruction of the department's counseling psychology classes. At about the same time, more training opportunities were made available to doctoral students from BYU's American Psychological Association-accredited clinical psychology program. As

we write this chapter, 22 of 50 therapists providing therapy at the CCC are supervised trainees: 2 postdoctoral, new-hire, or faculty residents; 4 predoctoral psychology interns; 2 paid clinical psychology student therapists; 2 paid counseling psychology student therapists; and 12 unpaid practicum students from counseling and clinical psychology.

The need to maintain accreditation and supervise 20 or more trainees has prompted closer examination of the quality of services offered. In 1992 we formed a research committee that designed a 23-item Counseling Services Satisfaction Questionnaire to provide supervisors and trainees with feedback about client satisfaction. The questionnaire is still used. CCC faculty also began to look for broader tools to evaluate the effectiveness of trainee services, prompting adoption of more systematic measurement of outcomes, which is discussed below.

Electronic Records

The university provided the CCC and its faculty with computers, network servers, and support for development of appointment management and record-keeping software in 1990. By 1996 the CCC had organized and recorded all psychotherapy, career advising, and academic support, using software developed by university information technology services. Therapists could access detailed records for all clients. Beginning in 2008, the CCC shifted therapy record keeping to the Titanium Schedule system, which was designed for use at university counseling centers. Electronic record-keeping systems allowed for reliable examination of psychotherapy-use patterns.

45-Item Outcome Questionnaire

In the early 1990s Mike Lambert and Gary Burlingame of BYU's clinical psychology department worked to develop a short and inexpensive but valid instrument focused on the problems most often treated with psychotherapy. They sought to standardize their instrument, the OQ-45 (Lambert et al., 2004) at the CCC, offering the CCC free use of the OQ-45 thereafter. CCC faculty later voted to adopt the OQ-45 for general use to evaluate outcomes. By 1996 all clients were routinely asked to complete the OQ-45 before each session. Compliance was and remains voluntary, but therapists are encouraged to monitor session-by-session outcomes.

In the beginning, the OQ-45 was hand scored. This was too time consuming to entice most therapists to persuade their clients to complete the instrument be-

fore every session. The CCC has since developed successively faster and more reliable scoring systems. Each step that simplifies and speeds scoring and communication of scores to therapists increases compliance. From 2003 on, the OQ-45 has been administered with handheld computers that can provide scores instantly. Technical developments that sped up and simplified scoring did the most to persuade therapists of the benefits of monitoring session-by-session outcomes.

Joining the Research Consortium of Counseling and Psychological Services in Higher Education

Joining the Research Consortium in its 36-university examination of distress and clinical outcomes increased pride of ownership in our research data. Faculty had already voted to adopt the OQ-45 and expressed confidence that the Research Consortium had also adopted it for their study. Faculty also found the PPC helpful and voted to adopt the PPC for use in initial paperwork completed by all new clients. Participation in the Research Consortium and use of the PPC established a greater sense of commitment to a research agenda.

Collaboration With Academic Departments

As CCC faculty grew more committed to research, clinical and counseling psychology doctoral students increasingly considered conducting dissertation research at the CCC. Dissertations based on data collected at the CCC have been especially powerful in encouraging collaboration. For each dissertation, there are at least two faculty committee meetings that are attended by CCC clinical faculty: one for the dissertation proposal, the other for the dissertation defense. Doctoral students' unique motivations to finish their dissertations can also facilitate completion of collaborative research. The pressures of providing clinical services can and do distract clinical faculty from research, but students completing dissertations are less likely to lose focus and momentum.

Student Life Research Funds

In 1997, Student Life, the university division to which the CCC belongs, began to offer small research grants to clinical faculty. This has been repeated annually over the past 12 years, providing CCC faculty with funds for research supplies, research assistants, and modest incentives. Funds are awarded to proposals submitted to

a CCC research management committee. As many as 30 proposals have been funded some years. Proposals are evaluated on several criteria: Will the proposed research improve services? Involve multiple CCC faculty members? Support scholarship for rank advancement? Support professional development? Improve training?

In addition to encouraging faculty research, funding has consistently supported part-time employment of two or more research assistants, usually a doctoral-level psychology student and an undergraduate psychology student. Student research assistant salaries consume the largest portion of research funding. Their work is a resource shared by most CCC faculty researchers during any given year. Research assistants have contributed to a consistent, symbiotic relationship similar to that seen in graduate departments. Students benefit from CCC faculty members' intimate knowledge and enthusiasm for their own research. Faculty, in turn, benefit from student researchers' familiarity with management and analysis of the data.

Responsiveness

Attempting to answer questions about psychotherapy has made it easier to answer many other questions about CCC practices. Several CCC faculty members have become adept at drawing information from our clinical archives to answer administrators' questions about demands for services over time. Dianne Nielsen's dissertation provided the CCC director with timely answers to university administrators' questions about the relationship between emotional disturbance and academic achievement, for example. CCC researchers have been able to provide support to other units at the university, providing, for example, assistance in scanning, scoring, and analyzing satisfaction and follow-up surveys.

A Facility Designed for the CCC

As university enrollment grew, CCC services outgrew available office space. Plans were formulated to move Student Life and the CCC to an enlarged student union building. In 1997 the CCC and dean of students moved to BYU's enlarged and redesigned Wilkinson Student Center. The center houses the university's large multiservice bookstore, two student recreation centers, several large meeting rooms and ballrooms, student employment services, a theater, headquarters for student clubs, a formal restaurant, a large food court, and several student-oriented service centers, including a post office, the lost and found, and a barber shop and hair salon. CCC facilities were built from designs proposed

by CCC faculty and include observation suites. It is estimated that as many as 40,000 students, faculty, staff, and guests pass through the Wilkinson Student Center on school days, placing the CCC in the center of university activity.

The Scientist-Practitioner Model

From 2000 on the CCC training committee moved from following a scholar-practitioner model to following a scientist-practitioner model of training and treatment. The decision was based on the CCC's habitual use of the OQ-45 as an empirical tool for measuring outcomes and validating practice. The majority of CCC faculty supported the training committee in this decision, revealing a commitment to a scientific orientation to our practice.

Faculty Goodwill

All CCC research initiatives, beginning with adoption of the OQ-45 as a center-wide measure of outcomes, proceeded through discussion and faculty vote. Though there have been few unanimous decisions, discord has been rare. Those in opposition have not been compelled or forced into major changes of practice.

AUTHOR NOTE

The research described in this chapter was made possible by more than 20 unnumbered research grants awarded to CCC faculty by the last two BYU Student Life vice presidents. Aaron Allred, Michael Campbell, Nathan Hansen, Cory Harmon, Erik Hawkins, Rachel Meibos, Karsten Slade, and Jason Whipple provided invaluable help gathering and managing the data analyzed.

Behavioral Genetics

Anna A. E. Vinkhuyzen
Sophie van der Sluis
Danielle Posthuma

Large individual differences exist among people in behavioral traits such as personality, cognitive ability, and psychiatric disorders. Some people are more sociable or more learned than others, some people are more likely to suffer from psychiatric disorders, and some are more likely to become addicted to stimulants like nicotine, alcohol, and drugs. Research in the field of behavioral genetics aims to understand the causes of these variations in behavior and disease.

Behavioral geneticists distinguish two major sources of inter-individual variation: genetic sources and environmental sources. The nature-nurture debate is founded on this duality and is concerned with determining the relative importance of innate abilities, versus the importance of personal experiences or environmental influences. The view that *nurture* is the single source of the observed variation in behavioral traits was favored by developmentalists in the 17th century. For example, John Locke (1632–1704) described the new born baby as a *tabula rasa* (“blank slate”) to emphasize his belief that humans are born “blank” and then shaped by their experiences and sensory perceptions of the environment. The *nature* view, on the other hand, emphasizes the relative importance of the innate variation in ability (i.e., of genetic factors). If a trait is heritable, then the closer the genetic relatedness of two individuals, the more these individuals will resemble each other in terms of that trait. This observation forms the basis of behavioral genetics research.

Although the nature-versus-nurture debate is still ongoing, it is generally accepted and has been shown for many clinical traits that both genetic and environmental factors are important in explaining individual differences.

In this chapter we describe how the relative importance of genetic and environmental influences can be quantified and how the actual genetic risk factors for a clinical trait can be detected. In addition, we describe a few more complex mechanisms that may underlie individual differences in complex traits, such as gene-environment interaction and correlation. We provide examples in the context of anxiety and depression, although similar methods can be applied to any other clinical trait.

SOURCES OF PHENOTYPIC VARIATION

In behavioral genetics it is assumed that the total variance (V_T) of a trait, also called the phenotypic or observed variance, can be decomposed into three sources of variation: one source of genetic variation (V_G) and two sources of environmental variation: shared (or common) environmental variation (V_C) and unshared (or unique) environmental variation (V_E):

$$V_T = V_G + V_C + V_E$$

V_G reflects all possible genetic contributions to the observed variation of a trait in the population—additive

genetic factors, dominance genetic factors, and effects of multi-gene interaction (*epistasis*; Bateson, 1909).

Shared environmental influences (V_C) are environmental factors that are shared by family members and render members of the same family more alike. The environments of individuals from the same family are more alike than the environments of individuals from different families. Shared environmental influences include shared experiences such as diet, socioeconomic status, and residential area.

Non-shared environmental influences (V_E) are environmental factors that create differences between members of the same family. In fact, it is the part of the phenotypic variation that cannot be explained by either genetic or shared environmental factors. Non-shared environmental influences include unique experiences such as relationships with friends and teachers and sports participation that are not shared with other family members. In addition, non-shared environmental influences may also be due to measurement error.

By dividing the estimates of the genetic or environmental variance components by the total variance V_T , we can standardize the three variance components. The standardized components are represented as:

$$h^2 + c^2 + e^2 = 1$$

where h^2 denotes the proportion of the phenotypic variation that is due to genetic factors (broad-sense heritability), c^2 denotes the proportion of the phenotypic variation that is due to the shared environment (factors shared by family members), and e^2 denotes the proportion of phenotypic variation that is due to the non-shared environment (factors not shared by family members).

Determining the relative proportions of different sources of variations for multiple traits has long been the major goal of behavioral genetics. Due to the rapid advances in genotyping technology, however, the goal has shifted toward detection of the actual genes that are important for a trait. Below, we briefly describe the classic research designs and methods applied in behavioral genetics as well as some of the more recently applied methods.

CLASSIC RESEARCH DESIGNS IN THE FIELD OF BEHAVIORAL GENETICS

Determining the Relative Proportion of Different Sources of Variation

To determine the relative influence of genetic and environmental factors on a trait, data are required from

individuals who are genetically and/or environmentally informative. Since actual gene finding or gene identification (or identification of influential environmental factors) is not the aim, there is no need to actually genotype individuals, as long as their genetic and environmental relationships are known. Three research designs are commonly used: the family design, the adoption design, and the twin design. Several extensions of the twin design allow researchers to deal with specific research questions.

In the *family design*, variation within families is compared to variation between families. The main question is, for example, whether biological brothers and sisters living in the same household are more alike than unrelated children of similar age. If family members resemble each other more with respect to a particular trait than unrelated individuals, then familial factors are expected to affect the individual differences in a particular trait. Family members, however, share both genes and common environmental factors, and therefore the family design does not allow for the disentanglement of these sources of variation.

In the *adoption design*, a distinction is made between genetic relatives and environmental relatives. Genetic relatives in the adoption design are family members who share (part of their) genes but do not live together. Environmental relatives are individuals who do not share genes but do share environmental factors as they share the same home environment. Phenotypic resemblance between genetic relatives living apart is evidence of genetic influences, while phenotypic resemblance between environmental relatives who do not share genes is evidence of shared environmental influences. The phenotypic resemblance, quantified as a correlation, between genetic relatives and environmental relatives can thus be used to determine the extent to which phenotypic variation is due to genetic or environmental factors.

Adoption studies are particularly informative when the adoptees are twins. Imagine the case of monozygotic (MZ) twins, that is, genetically identical twins who are adopted by two different families soon after birth. Although fairly rare, this situation is ideal for the estimation of the heritability of a trait: as the twins are genetically identical but reared in different environments, any resemblance between them is entirely attributable to genetic influences (h^2). The correlation between adopted MZ twins reared apart is therefore a direct estimate of heritability. In contrast, the correlation between MZ twins reared together is the result of both shared genes and a shared environment. The difference between the correlation of MZ twins reared together and the correlation of MZ twins reared apart is

therefore a direct estimate of the influence of the shared environment (c^2). The extent to which MZ twins reared together do not resemble each other is an estimate of the influence of non-shared environmental factors (e^2).

In addition, the correlation between adopted children and their adoption parents provides a direct estimate of shared environmental effects, while the correlation between adopted children and their biological parents provides a direct estimate of heritability. Comparing individuals from different generations is, however, not always optimal. As a result of cultural and age-related changes in environment and genetic expression, correlations between parents and children are likely to be lower than correlations between contemporaries. Such changes create differences between individuals from different generations, and as a result, genetic influences may be underestimated.

The *twin design* obviates the drawbacks of both the family design and the adoption design. The twin design makes use of the differences in genetic resemblance between MZ and dizygotic (DZ) twin pairs. MZ twins share 100% of their genetic material, while DZ twins, like pairs of regular sibs, share on average 50% of their genetic material. At the same time, when growing up in the same household, both MZ twins and DZ twins share 100% of their common environment. The correlation (i.e., the standardized measure of resemblance) between MZ twins can therefore be written as a function of the heritability and shared environmental factors:

$$r_{MZ} = h^2 + c^2$$

while the correlation between DZ twins, or regular siblings, equals:

$$r_{DZ} = \frac{1}{2} h^2 + c^2$$

From this, it follows that if the MZ twin correlation is larger than the DZ twin correlation, at least part of the resemblance must be attributed to genetic factors (see also Table 5.1).

Based on the observed MZ and DZ twin correlations as well as their known genetic and environmental relatedness, the relative proportions of genetic factors (h^2), shared environmental factors (c^2), and non-shared environmental factors (e^2) can be estimated as follows (Falconer, 1989):

$$\begin{aligned} h^2 &= 2*(r_{MZ} - r_{DZ}) \\ c^2 &= 2*r_{DZ} - r_{MZ} = r_{MZ} - h^2 \\ e^2 &= 1 - r_{MZ} \end{aligned}$$

Extensions of the Twin Design

The twin design is the most commonly used design in the field of behavioral genetics to evaluate the relative influence of genetic and environmental factors on a trait. This research design does, however, rely on several assumptions. First, it is assumed that DZ twins share on average 50% of their genes. This assumption is only tenable if both parents are random subjects from the population and do not have more genetic variants

5.1

Illustration of MZ and DZ Twin Correlations and Calculated Estimates of Genetic Effects and Common Environmental and Unique Environmental Effects

TWIN CORRELATIONS		rMZ	rDZ	h^2	c^2	e^2
rMZ = rDZ = 0	→ E	0	0	0	0	1
rMZ = rDZ > 0	→ E + C	.40	.40	0	.40	.60
rMZ = 2*rDZ	→ E + G	.60	.30	.60	0	.40
rMZ < 2*rDZ	→ E + C + G	.80	.65	.30	.50	.20

Notes: rMZ = twin correlation MZ twins; rDZ = twin correlation DZ twins; E = unique environmental effects; C = common environmental effects; G = genetic effects; h^2 = heritability; c^2 = proportion of the phenotypic variation due to shared environment; e^2 = proportion of phenotypic variation due to non-shared environment.

in common than would be expected by chance alone. In other words, it is assumed that mating occurs at random in the population and that partners do not select each other based on the trait under study. Second, it is assumed that MZ twins do not share more environmental factors than DZ twins; this is the so-called equal environment assumption. Third, it is assumed that all genes act in an additive way (i.e., that dominance genetic influences are absent). Fourth, it is assumed that genes and environment do not interact. In other words, genes do not affect an individual's sensitivity to an environmental factor, and the environment does not affect the expression of the genes. The phenomenon of gene-environment interaction will be discussed in more detail later in this chapter.

To illustrate, significant differences between MZ and DZ twin correlations were reported in a summary of early twin studies on the genetics of depression and bipolar disorder. For depression, average correlations of .40 and .11 were observed for MZ and DZ twins, respectively, suggesting the influence of genetic factors (Allen, 1976). For bipolar disorder, average correlations of .72 and .40 were observed for MZ and DZ twins, respectively, suggesting involvement of both genetic and common environmental influences.

Several extensions of the classic twin design have been proposed to deal with these assumptions, such as study designs that include the siblings, partners, or spouses of twins.

Adding non-twin siblings to a classic twin design allows researchers to investigate whether means and variances are equal in regular siblings and twins and whether the covariance between DZ twins equals the covariance between non-twin siblings. If the DZ covariance is different from the covariance between regular siblings, a special twin environment is implicated, which means that the shared environmental influences of twins differ from the shared environmental influences of regular siblings. These tests are important because only when twins are not different from siblings can findings from twin-based research be generalized to the general population. Moreover, including non-twin siblings in twin studies enhances statistical power to detect sources of variance due to genetic and environmental effects (Posthuma & Boomsma, 2000).

To test the assumption of random mating, the parents and spouses of twins can be included in a research design. Two types of non-random mating can be distinguished, both of which occur in human populations. The first form of non-random mating is known as inbreeding and refers to mating between biological relatives. The second form of non-random mating is known as assortative mating and occurs when mate selection is based on traits that may themselves be under genetic pressure.

It is known that for several traits, individuals prefer to choose mates whom they resemble phenotypically (Crow & Felsenstein, 1968). Assortative mating implies that spouses are more similar with respect to a trait than would be expected by chance alone, which will affect the level of that trait in their offspring. For example, an increased percentage of disorders in spouses of patients, compared to controls, is indicative of non-random assortment. Assortative mating has been shown to take place with respect to biological factors such as body height (Silventoinen, Kaprio, Lahelma, Viken, & Rose, 2003), but also for behavioral traits such as intelligence (Plomin & Loehlin, 1989), as well as for several psychiatric disorders. To illustrate, Maes et al. (1998) investigated assortative mating in the context of alcoholism, generalized anxiety disorder, major depression, panic disorder, and phobias. Findings suggested considerable associations between partners for most psychiatric diagnoses, and assortment was observed both within and between classes of psychiatric disorders. Variables that were correlated with the psychiatric diagnoses, such as age, religious attendance, and education, did explain part, but not all, of the assortment between partners.

Since assortative mating increases the genetic and environmental correlations between mates, estimates of the relative influence of genetic and environmental factors within a twin design will be biased if assortative mating is not appropriately accounted for. When parents are more genetically alike than expected by chance, the DZ twins genetic resemblance will on average be more than 50% due to transmission of the correlated parental genes. As a result, the resemblance of DZ twin pairs will increase relatively to MZ twin pairs. Unmodeled assortative mating will therefore result in artificially inflated estimates of the shared environmental component and an underestimation of heritability.

The presence of assortative mating can be studied by calculation of the phenotypic correlation between the parents of twins, or the phenotypic correlation between twins and their spouses, when spouses of the twins are included in the study, assuming that the extent of assortative mating does not change across generations. Thus, in an attempt to discern the relative contribution of the sources of variance of a particular trait, including parents or spouses of twins in the study design allows one to accommodate the effects that assortative mating may have on the estimates of the relative influences of genetic and environmental factors.

In the classic twin design, which includes only data from MZ and DZ twins, the influence of non-additive

or dominance genetic factors and shared environmental factors are confounded. Inclusion of parental data, or data from cousins of twins or children of twins, for example, allows for the simultaneous estimation of shared environmental effects (C) and dominance genetic effects (D).

Collecting data of parents or children of twins has several additional advantages. First, it enables one to distinguish between *genetic transmission* from parents to offspring and *cultural transmission* from parents to offspring. Genetic transmission refers to resemblance between parents and offspring that is caused by the genes that are transmitted from parents to their offspring, while cultural transmission refers to the resemblance between parents and offspring that is due to a home environment that is created by the parents. Cultural transmission increases resemblance between parents and offspring but also increases resemblance between twins and siblings. To complicate things even more, parents may create an environmental situation that is correlated with their own genotype or phenotype. For example, parents with a genetic liability to be anxious may create an overprotective home environment, which in turn may have a disadvantageous effect on the development of anxiety in their children. When cultural transmission exists in the presence of genetic transmission, environmental influences become correlated with genetic influences. In a classic twin design, where parental data are not available, cultural transmission cannot be modeled or estimated explicitly, and the effects of cultural transmission will end up as shared environmental variation. When parental information is available, the effects of genetic transmission and cultural transmission on familial resemblance can be explicitly distinguished.

Second, when parental data are available, researchers can test for the presence of correlations between genes and environment (gene-environment correlations). In the classical twin design, it is assumed that genetic effects and environmental effects act independently on the phenotype. When genes and environment are correlated, however, the effects of genes cannot be considered independent of the effects caused by environmental factors.

Third, comparing the estimates of the genetic and environmental effects obtained in studies in which parental data were or were not included, provides information about possible developmental changes in genetic and environmental influences between childhood and adulthood. For example, when the estimates of the additive genetic effects are not equal across the two designs, this may indicate that genes are of importance in

adulthood, while they have no function in childhood, or vice versa.

INTERPLAY BETWEEN GENES AND ENVIRONMENT

The classic twin design assumes that genes and environment act in an additive manner. It is, however, conceivable that individuals seek out, or grow up in, environmental situations that are somehow correlated to their genotype. For example, parents who are fond of sports will transmit their athletic genes to their offspring and in addition are likely to stimulate their children by joining a sports club or providing them with sports equipment such as a football or a baseball bat. In such a case, the environment that is created by the parents is correlated with the genotype of the children. Similarly, children who are genetically predisposed to become good athletes are likely to actively select environmental conditions in which their genetic disposition can become manifest. It is even possible that genes and environment interact. In that case, the effect that a certain environmental factor has depends on someone's genotype, or the extent to which genes come to expression depends on environmental conditions.

Gene-Environment Correlation

In general, in the presence of gene-environment correlation ($r_{(G,E)}$), the environmental factors that influence an individual's phenotype are not a random sample of the entire range of possible environments but are correlated with, or caused by, the genotype of an individual. Usually, three different types of gene-environment correlation are distinguished (Plomin, DeFries, & Loehlin, 1977): passive, evocative, and active $r_{(G,E)}$.

Passive $r_{(G,E)}$ refers to the situation in which parents transmit both genotypes and relevant environmental factors. For example, athletically gifted parents transmit genes that influence physical attributes such as strong muscles, a well-functioning hemoglobin system, and a healthy respiratory system. In addition, these parents also provide their children with an athletically stimulating environment, such as sports equipment and training facilities. Since the environment that is created by the parents is a function of the parents' genotypes, and each parent transmits 50% of his/her genes to the offspring, a correlation between the environment and the child's genotype is implicated.

We speak of evocative $r_{(G,E)}$ when the genetic predispositions of an individual evoke certain reactions

from the environment. For example, a child who shows talent for sports may be treated differently by his/her high school trainer than a child whose sports ability is average.

Active $r_{(G,E)}$ occurs when individuals create, or seek out, their own environments based on their genetic predisposition. For example, the child with the predisposition for being a good basketball player may seek out a high school or university with good sports facilities and a lively sports culture, because this will allow him/her to exercise, develop, and improve. That is, individuals with a certain genetic predisposition will select environments that fit their predisposition, that is, environments in which they can thrive and that are optimal for their predisposition to become manifest.

When $r_{(G,E)}$ is actually present, ignoring the gene-environment correlation in statistical genetic models and analyses may lead to biased estimates of the relative importance of both genetic and environmental factors (Eaves, Last, Martin, & Jinks, 1977).

Gene-Environment Interaction

Besides the possibility that genes and environment are correlated, it is also possible that environmental factors modify or trigger gene expression, or that someone's genetic makeup determines the effect that environmental stressors can have (Gene-environment interaction, $G \times E$). For example, traumatic experiences like life-threatening illness, molestation, and assault do in some victims cause severe depression, but not in all. It is conceivable that the actual effect of such extreme experiences depends on someone's genotype, that is, on one's genetic liability to become depressed.

When $G \times E$ interaction is present, sample-based estimations of the additive genetic effects (A), the shared environmental effects (C), and the non-shared environmental effects (E) do not accurately reflect what is going on. After all, the relative contribution of genetic and environmental factors to the explanation of the observed individual differences in the phenotype may be different for subjects with different experiences, or for subjects with different genotypes.

$G \times E$ is one possible explanation for discordance observed between MZ twins with respect to disease (e.g., one twin suffers from depression or schizophrenia, while the other twin does not). As MZ twins are genetically identical, they have, in theory, the same genetic predisposition, or the same genetic liability for disease. This liability could, however, be increased or decreased as a consequence of specific life experiences. In other words, it is conceivable that differences in life experi-

ences create differences in the extent to which genes come to expression, which in turn results in phenotypic differences.

Just like disregarding gene-environment correlation, ignoring the effects of existing $G \times E$ leads to biased estimates of the relative importance of genetic and environmental determinants. When $G \times E$ interaction concerns the interaction between genes and *shared* environmental influences, ignoring its presence results in overestimation of the effect of genetic factors on the phenotype. If $G \times E$ interaction concerns the interaction between genes and non-shared environmental factors, ignoring its presence will result in overestimation of the effects of the non-shared environmental factors (Eaves et al., 1977; Jinks & Fulker, 1970).

To illustrate, an increasing body of evidence supports the presence of $r_{(G,E)}$ and $G \times E$ in the context of complex psychiatric disorders (Caspi & Moffitt, 2006; Kendler, 2005). Caspi et al. (2003) reported an interaction between the 5-HT transporter gene (5-HTT) and stressful life events that appears to determine liability to depressive illness. Individuals with one or two copies of the short allele of the 5-HTT gene exhibited more depressive symptoms after experiencing traumatic life events than subjects who were homozygotes for the long allele. This finding has been replicated in several studies (Eley et al., 2004; Kendler, Kuhn, Vittum, Prescott, & Riley, 2005; Wilhelm et al., 2006; Zalsman et al., 2006).

Recently, Wichers et al. (2008) reported an interaction between the BDNF Met allele, the short allele of the 5-HTTLPR gene, and childhood adversity in a model of depressive symptoms. Childhood adversity had a greater impact on depression scores in adulthood among BDNF "Met" carriers than among BDNF "non-Met" carriers. Moreover, this interaction effect between BDNF and childhood adversity was more pronounced in subjects who were carriers of the short repeat allele of the 5-HTTLPR gene. In addition, carriers of the Met allele also reported significantly more childhood adversity than non-carriers, which suggests gene-environment correlation.

STATISTICAL METHODS APPLIED TO THE (CLASSIC) TWIN DESIGN

Although calculating the relative proportion of genetic and environmental influences on a trait based on comparisons of MZ and DZ twin correlations is straightforward, this simple framework has some disadvantages.

First of all, it does not allow for a test of the statistical significance of the genetic and environmental influences. For example, when the comparison of MZ and DZ twin correlations suggests a heritability of 10%, then one would want to know whether this 10% deviates significantly from 0%. Twin correlations provide neither confidence intervals of the estimated parameters nor a description of how well the twin model describes the observed data. In addition, missing data cannot be accommodated if estimates are based on twin correlations, and the information of family members other than twins cannot be accommodated in the model.

In behavioral genetic studies it is therefore customary to use estimation procedures implemented in structural equation modeling. Structural equation modeling is a flexible statistical technique for testing and estimating linear relationships between observed and latent variables, where latent variables are not measured directly but are estimated based on observed information. The latent variables are the unmeasured sources of variation, denoted by G, C, and E. Their regression on the trait can be deducted from the known relations between the G, C, and E factors in MZ and DZ twins (see Figure 5.1). How well the model depicted in Figure 5.1 describes the observed data is evaluated through the use of an iterative model fitting procedure (see, e.g., Neale & Cardon, 1992), which returns parameter estimates and their confidence intervals.

Multivariate Analyses of Twin Data

For many psychiatric disorders, comorbidity is the rule rather than the exception. An important question is why two traits covary—that is, what is the nature of this covariation? For example, depression and anxiety often coincide, but why is that? Is this comorbidity due to genes that influence both traits, or is it largely due to environmental factors that act as risk factors for both depression and anxiety?

Bivariate (or multivariate) twin models can be used to investigate to what extent two (or more) traits are influenced by the same set of genes (genetic correlation) or by the same environmental influences (environmental correlation). That is, not only the variance of a trait but also the covariance between traits can be decomposed into genetic and environmental sources of variation on the basis of twin data. Figure 5.2 shows a path model of bivariate twin data, in which the relationship between depression and anxiety is described in terms of correlation at a genetic and environmental level.

If in the example depicted in Figure 5.2, the correlation of the depression scores of one twin with the anxiety scores of the co-twin is higher in MZ twins than in DZ twins, then this suggests that the observed correlation between the two traits is mainly due to genetic factors.

To illustrate, much research has focused on the comorbidity of anxiety and depression. According to Gray

Figure 5.1 Path diagram for univariate twin data.

Figure 5.2 Bivariate twin design.

and McNaughton (2000), comorbidity of anxiety and depression can be explained in two ways. First, one disorder is an epiphenomenon of the other disorder. Second, the disorders partially share a genetic etiology. In a review of a large number of multivariate twin and family studies on comorbidity of anxiety and depression, Middeldorp, Cath, van Dyck, and Boomsma (2005) support both explanations for the covariance observed between anxiety and depression. Depression and anxiety are genetically closely related; the two traits are 86%–100% influenced by the same genetic factors.

Longitudinal Analyses of Twin Data

When it has been established that genetic factors do to some extent explain individual differences observed in a certain trait or multiple traits, a next question could be are these genetic influences stable over time and are the same genes involved at different stages of life? Costly longitudinal studies would be needed to answer this question. However, the stability of genetic influences over time is sometimes investigated by analyzing data at one point in time with a *cohort design*. In such a design, subjects from different age cohorts are assessed phenotypically. Analyzing the relative influence of genetic and environmental

factors in different age cohorts gives information about stability of the magnitude of genetic and environmental influences along those age cohorts. An advantage of the cohort design is that longitudinal data collection within one single-population sample is not required, which saves researchers a lot of time waiting for their subjects to grow older. A major disadvantage, however, is that this design does not allow for any conclusions on whether the genetic factors that explain variation in one cohort are the same as the genetic factors explaining variation in another cohort. Moreover, differences due to age are confounded with any other differences between the cohorts.

An example of a cohort-design is a study on the diagnosis of early- and late-onset major depression, as defined by the *DSM-III-R* (Lyons et al., 1998). Early-onset (before age 30 years) and late-onset (after age 30 years) major depression were both significantly affected by genetic factors (early onset $h^2 = .47$; late onset $h^2 = .10$) and non-shared environmental factors (early onset $e^2 = .53$; late onset $e^2 = .90$). The size of genetic effects was larger for early-onset major depression, while non-shared environmental effects explained more variance in late-onset major depression.

When longitudinal twin data are available, it is possible to investigate to what extent the contribution

of genetic and environmental factors to the observed phenotypic variability is stable over time, and to what extent genetic and environmental variation is time specific. However, longitudinal analysis has several disadvantages: the design is relatively expensive, data collection takes more effort and time compared to the cohort design, and longitudinal designs are prone to dropout. That is, participants are asked to participate in the study over a longer period of time, and considerable numbers of participants tend to withdraw from the study for reasons that may or may not be related to the study object itself.

To illustrate, in a longitudinal study of 3- to 12-year-old children, Boomsma et al. (2008c) determined the relative stability and change of genetic and environmental influences on anxiety and depression. Mother and father ratings of their child's behavioral, emotional, and social problems were collected at five different time points. Stability of anxiety and depression in childhood was relatively low from age 3 to later ages ($r \approx .30$ from age 3 to later ages); after age 7, the stability increased ($r = .67$ between ages 10 and 12). With age, the heritability of anxiety and depression decreased and the influence of shared environmental factors increased. Heritability estimates diminished from around 60% at age 3 to around 40% at age 12. Shared environmental factors accounted for only 8% of the observed variation at age 3 but increased to about 23% at age 12. The contribution of non-shared environmental factors increased from 29% at age 3 to 36% at age 12. Genetic factors accounted for about 50% of the phenotypic stability of anxiety and depression over time. Results suggested a relatively small overlap of genes that influence anxiety and depression in younger children (age 3–5) and an increased genetic overlap at later ages. Shared environmental influences on the stability of anxiety and depression were relatively large in younger children (around 50% for age 3–5) and reduced after age 7. This example of a longitudinal twin study shows that genetic and environmental variation may to some extent be time specific. It also shows that stability of traits such as anxiety and depression can be analyzed in terms of genetic and environmental factors.

This example shows a decrease in genetic influences on the variability observed in depression and anxiety across the life span. An explanation could be that life events such as accidents and illnesses and home-, education-, and occupation-related incidents accumulate over time. Such environment-related life events increasingly contribute to differences between individuals, and as a consequence, the relative influence of genetic factors decreases over time. In contrast, studies on the herita-

bility of cognitive abilities repeatedly show an increase in genetic influences across the life span (Ando, Ono, & Wright, 2001; Bartels, Rietveld, van Baal, & Boomsma, 2002; Boomsma & van Baal, 1998; Bouchard & McGue, 1981; Luciano, Wright, Smith, Geffen, Geffen, & Martin, 2001; Petrill, Lipton, Hewitt, Plomin, Cherny, Corley, & DeFries, 2004; Plomin, 1999; Posthuma, de Geus, & Boomsma, 2001). Increasing heritability over the life span could be due to genes that become active later in life, or to a decrease in the influence of environmental factors, as a result of which the relative contribution of genetic influences increases. Otherwise, relatively small genetic influences in childhood may have large effects later in life. While parents and teachers are important with respect to the intellectual development of a child, adults are likely to seek out their own intellectually stimulating environment, which may reinforce genetic differences.

RECENT DEVELOPMENTS IN BEHAVIORAL GENETICS: GENE FINDING

The behavioral genetics methods discussed so far are informative about the extent to which genes explain variability in human behavior. These family-based designs give information about the relative influence of genes on variation observed in a particular trait. However, these designs are not informative about which specific genes are involved, how many genes are involved, or even where the genes are that are involved, that is, in which (part of the) chromosome. After it has been established that genes are involved (i.e., that the trait under study is heritable), a reasonable next step is to verify which part of the human genome is involved (linkage analysis) and, more precisely, which specific genes are involved (association analysis).

Linkage Analysis

Once genetic factors have been shown to be of importance in explaining variation in a trait, the next goal is to localize the genes that are involved. The aim of linkage analysis is to discover the rough location of a gene region on the chromosome. Linkage analysis is based on the comparison of genetic relatives, such as siblings. The assumption of linkage analysis is that relatives who resemble each other more phenotypically will also resemble each other more genetically. In other words, siblings who resemble each other with respect to a particular trait, like depression, personality, intelligence, or

weight, will share more alleles on the genes that are actually involved in the trait under study than would be expected by chance alone.

Two types of allele sharing are distinguished: identical-by-state (IBS) and identical-by-descent (IBD). Alleles are IBS if they have the same DNA sequence (i.e., have the same form). Alleles are IBD if they have the same DNA sequence *and* the same ancestral origin (i.e., they are inherited from the same ancestor). Alleles that are IBD must be IBS, but alleles that are IBS are not necessarily IBD. Since offspring receive one allele from each parent, siblings can share zero, one, or two alleles IBD at a locus. For example, suppose a mother has genotype A1A2 and a father has genotype A3A3. Sibling 1 inherits A1 from his mother and the first A3 allele from his father, while sibling 2 inherits the same allele A1 from the mother, but the other A3 allele from the father. Both siblings have genotype A1A3, so their IBS status is 2. However, as the A3 allele is not exactly the same A3 allele, their IBD status is 1.

In behavioral genetics studies of quantitative traits, a causal gene is called a *quantitative trait locus* (QTL). However, rather than comparing siblings with respect to all QTLs on the genome, linkage analysis makes use of genetic markers. This genetic marker, or DNA marker, is a unique DNA sequence (segment of DNA) with a known position on the chromosome. For each participant, a number of markers are typed on each chromosome. These markers not only are informative about their own specific DNA sequence but indirectly also give information about genes lying close to this marker on the chromosome. Markers are indicative of adjacent genes because the marker alleles and the alleles of genes in close proximity are often inherited together, that is, as a block. So siblings who share marker alleles IBD—that is, they inherited the same allele from the same parent—most likely also share alleles on adjacent genes because they inherited the entire block of alleles from the same parent. If, however, the siblings only share the marker allele IBS—that is, the allele is physically the same, but it is not exactly the same allele—then the marker is less informative about the siblings' likeness with respect to adjacent genes, because the siblings did not inherit the same block of information.

We will not go into this in more detail, but it is important to understand that information about genes adjacent to the marker can be obtained from knowledge about siblings' IBD status at the marker: the IBD status at the marker reflects the IBD status at QTLs that are close to the marker. Differences observed between siblings with respect to the trait will be smaller if they share the same variant of a marker, obtained from the same

ancestor (IBD) (Haseman & Elston, 1972). If parental genotypes are not available, probabilities of IBD status of the offspring can be estimated based on allele frequencies in the population.

In many complex traits that are (highly) heritable, a large number of genes are expected to be involved, all with small effect. The shortcoming of linkage analysis with respect to the study of the genetic basis of quantitative traits is that it lacks power to detect genes of small effect. Another shortcoming of linkage is that it only gives information about an area in which a QTL may lie. These areas, however, are often still very large, covering hundreds of base pairs and often hundreds of genes. Linkage analysis thus provides a rough indication for where to look for the QTLs, but does not actually identify the QTLs.

To illustrate, results from linkage studies on anxiety and depression show significant linkage signals on several chromosomes (Boomsma, Willemsen, et al., 2008b). However, the replication rate of these studies is relatively low. This might be due to the relatively small sample sizes and different definitions of the phenotypes. For example, Holmans et al. (2007) reported linkage regions on chromosomes 8, 15, and 17; McGuffin et al. (2005) reported regions on chromosomes 1, 12, 13, and 15; and Middeldorp et al. (2008) reported linkage regions on chromosomes 2, 8, and 17. All these regions may thus contain one (or more) gene that contributes to susceptibility to anxiety or depression.

Association Analysis

Once the rough location of a gene region on the chromosome is identified, candidate genes can be selected from this region. In association analysis, it is subsequently tested whether these candidate genes are actually involved in the trait under study. This is done by testing whether the trait means are the same for all possible genotypes. For example, if a gene is diallelic, three genotypes—A1A1, A1A2, and A2A2—can be distinguished, and one can test whether the trait means are the same across these three genotype groups.

A commonly used approach in association analysis is the case-control design. Here, allele frequencies in a group of unrelated, affected individuals (i.e., patients or cases) are compared to the allele frequencies observed in a group of unrelated controls (healthy subjects). Alleles that are statistically more frequent in cases than in controls are thought to be involved in the disorder under study. Further research into the function of the gene is then required to establish whether the relationship between the allele and the disorder is causal in nature.

Association analysis is statistically powerful and therefore allows for the detection of genes with small effect. While linkage analysis is conducted within families, association studies are usually performed at a population level, which facilitates data collection. Furthermore, while linkage is usually genome wide, association studies were until recently limited to candidate genes, or candidate regions, as detected within a linkage study. Presently, however, completion of the Human Genome Project in 2003, the International HapMap Project in 2005, the 1000genomes project in 2009, and the decline in genotyping costs has made genome-wide association analysis feasible. In this approach, hundred thousands of DNA markers across the entire genome are scanned to find genetic variations associated with a particular trait or disorder.

It is important to note that although association studies are theoretically straightforward, they come with their own shortcomings. There are several reasons why genes can be statistically associated with a trait without being functionally related to the trait (this is called spurious association). Especially in genome-wide association, problems related to statistical power (e.g., sample size, multiple testing) are serious. Finally, practice shows that results obtained through association studies are often hard to replicate. This can be due to various reasons, such as difference between studies in the definition or measurement of the phenotype, differences between studies related to the sampling of participants, differences between studies of the origin of the participants (i.e., allele frequencies may differ between the countries in which the studies are conducted), and sample size.

Finally, once a gene has been statistically linked to a trait, it still remains to be seen how the gene is functionally related to the trait. The link between proteins and enzymes, on the one hand, and observed behavioral traits, on the other hand, is often far from clear, and the road from DNA sequences that code for specific enzymes and proteins to the behavioral trait under study is in itself a very long and very complicated one.

Behavioral Genetics and Clinical Practice

Discoveries in the field of human genetics have changed the general view on behavioral disorders dramatically. For example, until the 1970s, the development of ADHD was thought to be caused by poor upbringing. Nowadays, ADHD is known to be one of the most heritable childhood disorders, with heritability estimates around 70% (Jepsen & Michel, 2006). Likewise, liability to mood disorders such as depression and anxiety is influ-

enced by genetic factors as well (Hettema et al., 2001a, 2001b; Kendler, Gatz, Gardner, & Pedersen, 2006a, 2006b; Sullivan, Neale, & Kendler, 2000). Studies have been conducted on the genetic influences on many other behavioral disorders, of which schizophrenia is the most widely studied. Twin studies show heritability estimates of liability to schizophrenia of around 80% (Sullivan, Kendler, & Neale, 2003).

Since the completion of the Human Genome Project in 2003 and the International HapMap Project in 2005, countless studies have focused on gene finding for behavioral diseases. To date, many genes have been reported to be associated with bipolar disorder. The two most replicated genes in bipolar disorder are the same genes that are associated with schizophrenia (Farmer, Elkin, & McGuffin, 2007; Kato, 2007). Up to now, gene finding results for major depression and anxiety have been less encouraging. One of the reasons for this failure to detect and replicate genes might be that multiple genes of small effect are involved in these behavioral disorders (Harrison & Law, 2006; Jonsson, Kaiser, Brockmoller, Nimgaonkar, & Crocq, 2004; Li, Collier, & He, 2006; Straub et al., 2002).

Understanding the genetic architecture of behavioral diseases is expected to have two major benefits. First, an individual's genetic makeup provides information about his or her risk of developing a particular disease. This information is useful in prevention. For example, individuals known to have a greater risk of developing schizophrenia may be advised to avoid the use of hallucinogenic drugs. Second, an individual's genetic makeup may be of interest in the choice of treatment. Nowadays treatment is adapted to several factors, such as personality, gravity of the disease, and motivation and cooperation of the patient. Success of treatment may, however, also depend on individuals' genetic makeup, and adapting treatment to the genetic characteristics of patients may lead to higher improvement rates.

In physical diseases, selection of treatment based on genotype has already been introduced. Studies on breast cancer, for example, have shown that specific gene variants affect therapy outcome. For example, recurrence after tamoxifen therapy, a widely used endocrine therapy for estrogen-receptor-positive breast cancer, is dependent on genes that are related to metabolic enzymes (Wegman, Vainikka, Stal, Nordenskjold, Skoog, Rutqvist, & Wingren, 2005).

Identifying genes that are associated with behavioral disorders will allow us to gain insight into the etiology of the disease. Hopefully, this will lead to development of therapies that are maximally tailored to the clients' characteristics, including their genotype. Furthermore,

identifying genes that are associated with effects of medical treatment may lead to genotype-adjusted pharmacotherapy. For example, molecular genetic research on ADHD focused on candidate genes involved in the dopamine system that is associated with treatment with methylphenidate. Stimulant medications such as methylphenidate act primarily by inhibiting the dopamine transporter that is responsible for the dopamine reuptake. Small but significant associations have been reported for two dopamine receptor genes (Li, Sham, Owen, & He, 2006).

CONCLUDING REMARKS

In the majority of behavioral disorders, individual differences observed in liability for disease have been shown to relate to individual differences in genetic architecture. Heritability estimates range from very low (sleep problems $h^2 \approx 20\%$ [Boomsma, van Someren, Beem, de Geus, & Willemsen, 2008]) to very high (autism $h^2 \approx 90\%$ [Freitag, 2007]). Many studies report higher heritability estimates for more severe manifestations of disorders and for early onset manifestations of disorders. For example, both depression and anxiety show higher heritability estimates for more severe forms and for early-onset forms (Hettema et al., 2001a; McGuffin, Katz, Watkins, & Rutherford, 1996; Scherrer et al., 2000). Higher heritability estimates were also reported for more severe manifestations of schizophrenia (Gottesman, 2001). Moreover, genetic influences are larger for type 2 schizophrenia, which is known for passive symptoms such as withdrawal and lack of emotion, than for type 1 schizophrenia, which is known for active symptoms such as delusions and hallucinations (Dworkin & Lenzenweger, 1984). In general, type 1 schizophrenia has a better prognosis and a better response to medication.

The finding that more severe manifestations of disorders are more heritable raises questions on whether, for example, the same genes are associated with different manifestations of a disorder. Since development is a result of a constant interplay between genetic and environmental factors, neurodevelopmental disorders like schizophrenia, especially the late-onset type, might be the result of interplay between genes and environment. Insight into this interplay will lead to a better understanding of the expression of genes.

In recent years, behavioral disorders are assessed as a quantitative feature instead of a dichotomous feature. That is, researchers have focused on a continuum from mild to severe depression symptoms, rather than on a dichotomous distinction between participants with

and without depression. When focusing on continua, behavioral disorders are considered the quantitative extreme of the same genetic and environmental factors that contribute to the phenotypic variation observed within the normal range of behavior. Analyzing behavioral disorders as a quantitative feature may require the inclusion of individuals who are not actually diagnosed for the disorder but do suffer from some of its symptoms. These individuals can be informative since they are expected to be carriers of associated genotypes.

A quantitative view on disorders is also useful in finding genes that are associated with multiple disorders. It has been shown that phenotypic, but also genetic, comorbidity is common in numerous behavioral disorders. For example, genes associated with bipolar disorder are known to be associated with schizophrenia as well. However, according to *DSM* criteria, bipolar disorder is only diagnosed when schizophrenia is not, which precludes comorbidity studies if diagnostic dichotomies are used as input, rather than quantitative measures. When participants with symptoms of both disorders are neglected in gene-finding studies, a lot of potentially valuable information is lost. In addition, it is possible that analyzing disorders as a continuum may lead to the identification of QTLs that contribute to individual differences in the disorder itself.

The recent technological improvements, available financial funding, and intended close cooperation with fields like molecular biology and functional genomics make behavioral genetics at present one of the most rapidly changing and evolving fields in science.

Sleep Medicine and Sleep Disorders

Maxime Bonjean
Carl Stepnowsky
Thien Thanh Dang-Vu
Terrence J. Sejnowski
Pierre Maquet

Over the centuries, sleep was first viewed as a mirror of death, and later as a passive state with a suspension of activity (i.e., the *absence* of consciousness). Today, while we know that sleep is an active state and involves a complex and highly organized series of physiological and behavioral states, some aspects of sleep still remains a mystery.

Many people recognize that spending more than one-third of a normal human life sleeping has a functional significance, while some still see it as a waste of time dramatically impeding productivity. Currently, the prevalence of sleep disorders is increasing in Westernized societies, where the potential for independence from natural influences on sleep, such as exposure to sunlight, is combined with social and economic pressures to shorten the time spent asleep.

As we will see in this chapter, the fact that our society has such little regard for sleep leads to a dangerous and unsustainable situation, with multiple health consequences. Denying the central role that sleep occupies in life is denying its role in our immune defense, cognitive performance, and mental health. It is also denying the impact of sleep disorders in a broad range of interconnected pathologies, including poor vigilance and

memory, reduced mental and physical reaction times, reduced motivation, depression, insomnia, metabolic abnormalities, obesity, immune impairment, and even increased risk of cancer. There is an intimate connection between these pathologies and the way in which we have organized our society in recent years.

During the last 20 years, we have witnessed, both in the United States and in Europe, the gradual emergence of a specific medical field for sleep and its related disorders through a remarkable increase of knowledge about sleep and sleep disorders, due to the new developments in genetic, immunological, neurophysiological, and neurochemical techniques. Understanding these mechanisms is a prerequisite to understanding sleep disorders. Some major challenges and fundamental questions still have to be resolved, such as the purposes and functions of sleep, which are among the most difficult problems of neuroscience and biology.

Sleep disorders occur at a high prevalence and are highly diverse, with insomnia, sleep apnea, and hypopnea being the most prevalent. Indeed, currently more than 80 sleep disorders have been identified, defined, and listed (American Academy of Sleep Medicine, 2005). Patients' awareness, physicians' diagnoses, and

subsequent treatments are not always at the optimum; sleep disorders thus require a multidisciplinary approach as well as better medical instruction.

Sleep medicine is such a broad topic that we had to make some crucial choice in selecting the topics to fit in a chapter. Therefore, the aim of this chapter is not to substitute for a textbook or to be exhaustive, but to provide a balanced and up-to-date introduction.

The first part of this chapter deals with the fundamentals of sleep, taking a neuroanatomical and cellular emphasis in order to help readers understand how neuronal networks and neurotransmitters control and regulate non-pathological sleep. The second part deals with some of the most prevalent and invalidating sleep disorders. The chapter places a specific emphasis on pharmacological treatment.

FUNDAMENTALS OF NON-PATHOLOGICAL SLEEP

Nature of Sleep

Sleep is identified on the basis of an individual's behavior and brain electrical activity.¹ Formally, sleep is defined as a natural periodic state of bodily rest characterized by a readily reversible suspension of consciousness of the external world and reduced awareness and responsiveness. In humans, this is characterized behaviorally by a reclined position, closed eyes, decreased movement, and decreased responsiveness to internal and external environment (Markov & Goldman, 2006). However, the decreased responsiveness is *selective* and the brain continues to process some sensory information during sleep, and some meaningful stimuli are more likely than others to produce arousal.

From a metabolic point of view, though it represents only 2% of the whole body mass, the brain consumes up to 20% of metabolic activity, producing a ratio weight/energy of 1:10. Surprisingly enough, this metabolic ratio is roughly constant regardless of the state of brain activity. Even more interesting, during sleep the brain is highly active and its corresponding metabolic activity is far from significantly reduced (Dang-Vu et al., 2008).

The amount of sleep that a person needs is affected by several factors, and there exists a significant individual and night-to-night variability. Age, genetics, and

homeostatic pressure (sleep debt) may all play a role in determining sleep length and quality. The distribution of sleep hours across the population follows a remarkably Gaussian distribution, spanning from about 5 to 11 hours, with an average length of sleep of approximately 7.75 hours per night. Though sleep is ubiquitous in the animal kingdom and has been observed in all mammals, including humans, without exception (Siegel, 2008), animals have different sleep needs than humans (Figure 6.1). Jim Horne from Loughborough University's Sleep Research Centre has suggested that the amount of sleep we require is what we need not to be sleepy in the daytime. Indeed, sleep restriction results in daytime sleepiness, and daytime sleepiness suggests that an individual's sleep needs have not been met (Sinton & McCarley, 2004). The world record for the longest sleep deprivation was set in 1963 by Randy Garder, a 17-year-old high school student from San Diego, with 11 days (264 hours) of continuous deprivation. Irritability, delusion, and tremors were observed successively during the course of the experience. Following a first night of sleep, lasting 15 hours, his symptoms mostly disappeared, and within a week, he was behaving normally without apparent lasting harmful effects.

The popular classical view of sleep as a passive resting state for the brain during which it is "switched off" was invalidated in the 1930s when Harvey and Loomis, and successively Nathaniel Kleitman (1939), described a very organized, typical, and reproducible pattern of electroencephalogram during sleep. They discovered that sleep comprises different stages that repeat in characteristic patterns throughout the night. In 1953, Aserinsky and Kleitman identified REM sleep. Following that, Rechtschaffen and Kales (1968) published the very first manual outlining the criteria for identifying and scoring sleep, which was revised in 2007 by the American Academy of Sleep Medicine (2007) with an update on the staging rules.

Based on electrophysiological recordings, Rechtschaffen and Kales (1968) were able to distinguish between the three major states of consciousness: (1) wakefulness, (2) REM sleep (rapid-eye movement sleep), and (3) non-REM sleep. They divided non-REM sleep into four different stages.²

There is a continuum in the EEG as the subject falls asleep and enters the different sleep stages. The transitions between these sleep stages can be neither clearly

1. This chapter will focus on human sleep, though some comparisons, parallelisms, and differences with animals (mostly rodents or other mammals) may be discussed.

2. The authors of the revised manual published in 2007 lumped together stages 3 and 4, leaving only 3 major distinguishable non-REM sleep stages.

nor easily defined. The distinction between the different stages might seem somewhat arbitrary. The next section describes some electrophysiological characteristics of these different sleep stages.

Stages of Sleep

In homeotherms, sleep consists in a succession of two major recurrent states, rapid-eye movement (REM) sleep and non-REM (NREM) sleep. NREM sleep consists of three stages: stage I, stage II, and stage III. NREM sleep accounts for 75%–80% of sleep time, and REM sleep accounts for the remaining 20%–25% of sleep time (Shneerson, 2000).

Sleep and wakefulness are subjective behavioral phenomena. Therefore in order to identify and quantify them in an objective manner, sleep researchers and clinicians generally rely on three fundamental measures. These measures are the physiological measure of (skeletal) muscle tone (electromyogram, EMG), eye movement (electro-oculogram, EOG), and brain electrical activity (electroencephalogram, EEG). In clinical routine in sleep medicine, it is also common and useful to assess four additional variables: monitoring of cardiac activity (electrocardiogram, ECG), airflow (at the nose and mouth), non-invasive oxygen saturation, and respiratory effort. The EEG reading is the most impor-

tant measure in differentiating between the NREM sleep stages, while EMG and EOG are most important in differentiating REM sleep from NREM sleep.

Wakefulness is characterized by EEG desynchronization, EMG tone, and consciousness (Mignot, 2008). The EEG pattern of restful wakefulness is characterized by the predominance of alpha power activity (8–12 Hz), as shown in Figure 6.2. Restful wakefulness is progressively replaced by drowsiness, technically called stage I of NREM sleep, and alpha rhythm progressively transforms to a lower frequency corresponding to the theta rhythm (4–8 Hz). Stage I of NREM sleep is a short transitional state lasting only a few minutes (< 10 minutes) between drowsy wakefulness and deeper sleep stages (stages II–III). The eyes move slowly under the eyelids, muscle activity decreases, and the arousal threshold is low.

Stage II of NREM sleep is a period of light sleep, beginning typically within 12 minutes following sleep onset, and is the state in which we spend the most of our sleep time (about 45%–55% of total sleep time). It has a very distinctive EEG pattern (see Figures 6.2 and 6.3), in which specific oscillatory patterns termed sleep spindles and K-complexes dominate. Sleep spindles are the hallmark of stage II NREM sleep, with a waxing-and-waning oscillation at the frequency of 11–15 Hz, lasting 0.5 second to 3 seconds, and recurring several times per

Figure 6.1 Average total sleep time per day across animal species. Body size appears to be a major determinant in the amount of sleep that a species needs. In general, the larger the animal, the less sleep it requires.

Figure 6.2 Schematic illustration of the different brain electrical activities assessed by EEG throughout sleep. Human sleep is characterized by the alternation of REM and NREM sleep, the later being further divided into four qualitatively distinct stages, corresponding to increasing depth of sleep which is reflected by a concomitant increase in EEG amplitude and decrease in frequency.

From "The Neurobiology of Sleep: Genetics, Cellular Physiology and Subcortical Networks," by E. Pace-Schott & J. Hobson, 2002, *Nature Reviews Neuroscience*, 3(8), p. 600. Copyright ©2002 by Macmillan. Adapted with permission.

minute. Sleep spindles are believed to have a thalamic origin and are suspected to play a crucial role in the memory enhancement hypothesis of sleep. K-complexes, which interleave sleep spindles during stage II, are sharp waves with large deflection at a frequency of less than 1 Hz and are reminiscent of the slow-wave oscillation that is mostly dominant during slow-wave sleep (i.e., stage III). Their origin is still not fully understood. During stage II, the heart rate slows, and body temperature decreases. At this point, the body prepares to enter deep sleep.

What is now categorized as stage III (stages III and IV in Rechtschaffen and Kales's terminology) is referred to as deep sleep or slow-wave sleep (SWS). We spend about 15%–20% of our total sleep time in this state. The EEG is characterized by delta waves, which are synchronized, high-amplitude ($> 75 \mu\text{V}$), and slow frequency (0.5–4 Hz) oscillations. The stages formerly referred to as stages III and IV are distinguished by the amount of delta waves present ($< 50\%$ for stage III, and $> 50\%$ for stage IV; see Figure 6.2), although this distinction is not made by the new classification (American Academy of Sleep Medicine, 2005). As sleep deepens, moving toward slow-wave sleep, the arousal threshold increases. Muscle tone assessed by EMG decreases (while remaining at all time greater than during REM sleep) between stages I and III, and NREM sleep is characterized by the

absence of eye movement recorded by EOG. Immune functions increase during deep sleep.

REM sleep, also known as paradoxical sleep, has a totally different polysomnography characteristic. EEG is desynchronized and characterized by a low-voltage, mixed-frequency activity with slow alpha and hippocampal theta rhythms (Mignot, 2008; Shneerson, 2000). This is the stage of sleep the most associated with dreaming. Distinguishing REM sleep from relaxed wakefulness on the sole basis of a visual inspection of the EEG is not very straightforward—if not impossible—since it is also characterized by desynchronized low voltage and fast frequencies in the alpha-rhythm band. Based on EEG, EMG, and EOG characteristics, REM sleep can be separated into tonic REM sleep, during which skeletal muscle tone is absent (muscle atonia), and phasic REM sleep, during which there are intermittent bursts of ocular movements (hence the name "rapid-eye movement") measured by EOG, myoclonic twitches, transient swings in blood pressure, heart-rate variability, and irregular respiration (Shneerson, 2000). Transient apnea or hypopnea as well as most of the dreaming period occur during REM sleep (Shneerson, 2000). During REM sleep, muscle atonia of striated muscles is believed to occur mostly via glycinergic inhibition of somatic motoneurons located in the spinal

Figure 6.3 NREM sleep stages II and III, REM sleep, and their associated polysomnographic measures (EEG, EOG, and EMG).

cord.³ Respiratory muscles, along with the muscles of the eyes and the middle-ear muscles, remain active in REM sleep, unlike the submental muscles (muscles of the chin and neck). Dysfunction in this muscle inhibition can be responsible for REM sleep disorders associated with movements during dreaming.

Figure 6.4 synthesizes other important physiological measures typical of late-night sleep, such as eye movements (prominent during phasic REM), systolic blood pressure, respiration, cardiac pulse, and body movements. The most remarkable findings are the differences in physiological activity between REM and NREM cycles. The limited eye movement and decrease in muscle tone, heart rate, and respirations that characterize NREM sleep reach their lowest levels during stage III sleep. REM sleep is characterized by rapid, darting movements of the eyes, along with paralysis of most major muscle groups. Heart rate and respirations increase almost to the level found during wakefulness. Greater variability in these physiological constants is observed during REM sleep.

Sleep Architecture

Non-pathological sleep usually begins with a NREM sleep episode, followed by a period of REM sleep.

The alternation of episodes of NREM and REM sleep is called a sleep cycle (NREM-REM cycle), lasts about 90 minutes, and recurs three to seven times in the course of the night.

The hypnogram in Figure 6.5 describes the fluctuation of the different stages across a sleep night. The length of each bar denotes the duration of each stage. The distribution of stages is, however, unequal throughout the night: early in the night, NREM sleep is prominent and deeper than REM sleep and constitutes the main sleep activity (up to 80%). During the second half of the night, NREM sleep is shallow, and the proportion of REM sleep gradually increases during each subsequent cycle (Pace-Schott & Hobson, 2002).

The cyclic organization of sleep varies within and between animal species. The length of each REM-NREM epoch increases with brain size across species, and the depth and proportion of the NREM phase in each cycle increases with brain maturation within species. NREM sleep complexity is a function of brain systems, such as the thalamocortical circuitry, which reach maximum development in mature humans only to decline in post-mature age. It can therefore be concluded that the differentiation of sleep is a function of brain differentiation, a rule that indicates both mechanistic and functional links between sleep and other brain functions (Pace-Schott & Hobson, 2002).

It is important to remember that the sleep architecture described here corresponds to the sleep experienced by a normal healthy adult. Sleep architecture

3. This view has, however, recently been challenged (see Brooks, & Peever, 2008) and the subsequent dissenting opinions in the November 2008 issue of *Sleep*.

Figure 6.5 Hypnogram showing the alternation of sleep stages throughout a sleep cycle.

is variable and affected by several agents. Sleep disorders may affect the quality, duration, onset, or offset of sleep. Sleep deprivation, frequent sleep schedule shift, stress, and environment all affect the progression of the sleep cycle. Finally, sleep architecture, quality, and duration are naturally affected by age.

Effect of Age

Age is a major factor affecting sleep architecture. Sleep duration, depth, and the relative proportion of various stages vary across individuals and are function of age. In Figures 6.6a and 6.6b, which represent the evolution of total sleep time across the life span, we can see that total sleep duration decreases gradually, mostly due to NREM deep sleep, which progressively vanishes.

Indeed, neonates spend most of their time sleeping, and a large proportion of that time is spent in REM sleep (> 50% of total sleep time), while REM sleep is reduced in the elderly. In contrast, slow-wave oscillations are almost nonexistent in neonates and the elderly but reach a maximum peak in young adults. A sleep cycle, which lasts usually 90 minutes in normal healthy adults, does not last more than 50 to 60 minutes in newborns. The elderly experience more awakenings after sleep onset and sleep fragmentation than young individuals, as demonstrated by multiple

awakenings throughout the night—that is, the inability to maintain continuous sleep at night and wakefulness during the day.

The prominent presence of REM sleep among neonates and infants has led to the hypothesis that this specific stage must serve a developmental purpose, though it is not clear exactly what role it serves.

REGULATION OF SLEEP

Although a hallmark of sleep is the (apparent) suspension of activities that take place during the awake state, sleep is more than the absence of wakefulness; it is a regulated (and regulatory) process. For example, an ultradian process occurring during the sleep episode drives the alternation of the two basic NREM and REM sleep states and determines the proportion of the NREM-REM sleep cycle spent in REM sleep. Whether an individual is awake or asleep depends on the balance of forces promoting and inhibiting each of these two states (Johns, 1998). The timing, duration, and depth or intensity of sleep are believed to be regulated by the interaction of two independent major basic processes. This is called the two-process model (Achermann & Borbély, 2003; Borbély, 1980, 1982), the formulation of which occurred as a result of the work of Alexander Borbély

Figure 6.6 (a) Impact of age on sleep architecture. (b) Impact of age on total sleep time.

From "Normal Sleep and Circadian Rhythms: Neurobiologic Mechanisms Underlying Sleep and Wakefulness," by Markov & Goldman, 2006, *Psychiatric Clinics of North America*, 29(4), p. 845. Copyright ©2006 Elsevier. Adapted with permission.

(1980, 1982; Daan, Beersma, & Borbély, 1984). The two-process model consists of (1) a homeostatic process (or intrinsic drive) that is related to the amount of prior sleep and wakefulness and maintains the duration and intensity of sleep within certain boundaries and (2) a circadian rhythm, which is an endogenous rhythm with a periodicity of around a day and is generated by an internal pacemaker (biological clock) that determines the timing of sleep (Figure 6.7). The relationship between the two processes has been formulated as follows: “A Process S, the homeostatic process, increases as an exponential saturating function during wakefulness and decreases as an exponential function during sleep. Slow-wave activity in NREM sleep is the marker for the decrease of Process S.”

Figure 6.7 The three main processes involved in the regulation of sleep: homeostatic, circadian rhythm, and ultradian rhythm. As sleep progresses throughout the night, the intensity of NREM sleep declines and the duration of successive REM sleep epochs increases. (W: Wake; S: Sleep; N: NREM sleep; R: REM Sleep).

Homeostatic Process

Sleep homeostasis is one of the basic principles of sleep regulation (Tobler & Achermann, 2007). It is a regulatory system that enables organisms to compensate for the loss of sleep or surplus sleep. Homeostatic process is the progressive build-up of sleep pressure during wakefulness, which increases exponentially and is proportional to the time spent in prior wakefulness, reaching a peak at sleep time. Its strength then declines—again exponentially—once sleep is initiated, with the lowest point when one awakens in the morning. Thus it depends on immediate history—the interval since the previous sleep episode and the intensity of sleep during that episode.

Sleep homeostasis characterizes the increased sleep need and consequent sleep rebound after sleep deprivation. Indeed, a sleep deficit elicits a compensatory increase in the intensity and duration of sleep, while excessive sleep reduces sleep propensity. The homeostatic process or drive is therefore a direct indicator of sleep pressure. The time course of the homeostatic process can be derived from the changes of slow-wave activity from the EEG, which exhibits a global declining trend during sleep and the level of which in the first NREM sleep episode increases as a function of the duration of prior waking.

Figure 6.8 illustrates simulations of the homeostatic process (process S). Baseline wakefulness and sleep are depicted, as well as the impact of daytime nap and sleep deprivation on sleep pressure.

Genetic and Molecular Correlates of the Homeostatic Drive

It is known that sleep deprivation causes behavioral, physiological, and molecular changes. For instance, the magnitude of synchronized forebrain activity in the delta frequency band (0.5–4 Hz) is directly correlated with preceding time spent awake and is a direct indicator of sleep homeostatic pressure. Although we have much knowledge about the neuronal mechanisms controlling the transition from wakefulness to sleep, the genetic and molecular underpinnings of the homeostatic mechanism are still poorly understood (Tobler & Achermann, 2007).

It is widely believed that there is a sleep factor (or perhaps several sleep factors) that accumulates during wakefulness and dissipates during sleep. Many neurotransmitters and neuropeptides must be involved in sleep regulation, but one such substance, adenosine, a neurotransmitter, is gaining increasing attention. Ma-

Figure 6.8 Homeostatic process increasing in a saturating exponential fashion during waking, and declining exponentially during sleep (solid line = baseline with an 8-hour sleep episode; thick dashed line = sleep deprivation and recovery sleep after 40 hours of wakefulness; thin dashed line = 2-hour nap from 6 PM–8 PM and subsequent nighttime sleep).

nipulation of the adenosine system (for example, adenosine A1 receptor) leads to changes in sleep (Basheer, Strecker, Thakkar, & McCarley, 2004). Recently, accumulation of adenosine in the brain has been proposed as a sleep-promoting mechanism, although researchers have also proposed that other endogenous sleep factors, such as prostaglandin PGD2 and cytokines, contribute to the homeostatic regulation of sleep. As a consequence of sleep deprivation, the homeostatic process reaches a high level due to the extended period of waking state, and since the circadian rhythm is unaffected by this history, the sleep pressure is more intense.

The level of excitatory glutamate neurotransmitter release is highest when one is awake, and this, in turn, increases local adenosine release, resulting in adenosine A1 receptor activation. Local adenosine release has also been related to other perturbations that alter the metabolic state of neurons. This activation facilitates synchronized delta frequency oscillations during SWS. It has been demonstrated that the adenosine A1 receptor activation mediates the wakefulness-related feed-

back mechanism for the homeostatic sleep response (Sahin, Galdi, Hendrick, Greene, Snyder, & Bibb, 2007). Since adenosine A1 receptor activation is increased by adenosine release, these findings provide a mechanistic link between neuronal metabolic state and homeostatic sleep response.

Caffeine, an adenosine antagonist, is the most popular wakefulness-inducing and wakefulness-maintaining substance worldwide. Caffeine reduces slow-wave activity in the subsequent sleep episode, and caffeine consumption during prolonged wakefulness counteracts the typical effects of sleep deprivation on the waking and sleep EEG (Landolt et al., 2004). The effects of caffeine may be mediated both by inhibition of wake-promoting neurons via adenosine A1 receptors, and activation of sleep-promoting neurons via indirect effects on adenosine A2A receptors (Basheer et al., 2004). However, another study in rodents suggested that caffeine-induced wakefulness depends exclusively on adenosine A2A receptors (Huang et al., 2005).

A recent study identified a new protein, called sleepless (SSS), that is required for homeostatic sleep

pressure in the fruit fly *Drosophila melanogaster* (Koh, Joiner, Wu, Yue, Smith, & Sehgal, 2008). The loss of this protein caused a reduction to 15% of normal sleep levels in the *Drosophila melanogaster*. The authors of the study propose that the sleepless protein might link homeostatic sleep drive to neuronal excitability by regulating the amount and the activity of Shaker-dependent K⁺ channels. Although no SSS homologue has been yet identified in mammals, functional homologues might be found in the future.

Circadian Process

The circadian process maintains a 24-hour rhythm in sleep propensity (Mignot, 2008). It is influenced by an internal signaling system (the suprachiasmatic nucleus, often referred to as an “internal biological clock”) and an external signaling system, that is, a light-dark cycle (Borbély & Achermann, 1999), and is responsible for the alternation of periods with high and low sleep propensity. It functions independently of the homeostatic process.

Rhythms are ubiquitous in living species. Derived from the Latin *circa* (“around”) and *diem* or *dies* (“day”), circadian rhythms are biological rhythms that are present in the metabolic, physiologic, and behavioral processes of living beings throughout phylogeny, from cyanobacteria to unicellular organisms and humans (Silver & Lesauter, 2008). These rhythms are believed to allow organisms to anticipate and prepare for regular environmental changes.

Circadian rhythms have been found in all measurable physiological and behavioral responses, including sensitivity to external stimuli, motor activity, and motivated and emotional behaviors (Silver & Lesauter, 2008). They control body temperature, heart activity, hormone secretion, blood pressure, oxygen consumption, metabolism, the level of substances in our blood (i.e., red blood cells and blood sugar), gases, and ions such as potassium and sodium (Figure 6.9). They may even influence our mood, for example, in the form of wintertime depression known as seasonal affective disorder (SAD).

The circadian rhythm is remarkable because it drives sleep and arousal. It has been shown that time-of-day modulations can affect performance on a wide range of cognitive tasks measuring attentional capacities, executive functioning, and memory (Schmidt, Collette, Cajochen, & Peigneux, 2007; van Dongen & Dinges, 2003). More specifically, there is a daily peak approximately 4–8 hours after wake-up time (and a daily nadir during the latter half of the usual sleep time) in objective and subjective measures of alertness and performance

(indexed by psychomotor, vigilance, and memory tasks) and attention (indexed by psychomotor, vigilance, and memory tasks as well as ability to concentrate, subjective alertness, and cognitive performance). A circadian component has been found in learning, with the circadian system modulating memory formation in phase with the animal’s activity period—even in aphasia—suggesting a general phenomenon in many types of long-term learning (Silver & Lesauter, 2008).

Circadian rhythms are endogenous since they can persist in the absence of any environment cues. An internal “master clock” (or pacemaker) drives these circadian rhythms. In mammals, this function is fulfilled by the suprachiasmatic nucleus (SCN), which is composed of about 20,000 neurons and is situated bilaterally in the anterior hypothalamus, just above the optic chiasm (Figure 6.10). Though endogenously generated, these rhythms are entrained and synchronized by external timing cues (zeitgebers) under normal circumstances. One of the most prominent is the daily light-dark cycle, which sets the 24-hour rhythm by entraining the SCN with an excitatory modulation of the retinal cells via the retinohypothalamic tract (the pathway running from the retina to the SCN). Light hitting the retina activates the release of glutamate through the retinohypothalamic tract, projecting to the SCN (Berson, Dunn, & Takao, 2002).

Inputs and Outputs to the SCN

The SCN receives direct photic inputs from the retina through the retinohypothalamic tract, the fibers of which synapse on vasoactive intestinal polypeptide and gastrin-releasing peptide cells. Outputs of the SCN (efferent connections) are largely restricted to nearby hypothalamic regions, including the subparaventricular zone, the preoptic area, and the dorsomedial hypothalamus.

Circadian rhythms drive and regulate sleep, but they are not responsible for sleep. Lesions of the SCN in rodents did not prevent them from sleeping but instead resulted in the loss of circadian rhythms in sleep and wakefulness, which disrupted their sleep time, as well as hormone secretion, physiology, and behavior (Figure 6.11). Moreover, transplant from a mutant strain with a 22-hour circadian rhythm led to the establishment of the foreign rhythm in the host animals with ablated SCN, indicating that the SCN is necessary and sufficient for governing the circadian oscillations.

The release of melatonin from the pineal gland, signaled by the circadian rhythm, peaks at dawn and dusk. The SCN contains melatonin receptors, and the circadian clock can be reset by melatonin through a

Figure 6.9 Circadian rhythms and the body. Different body functions rise and fall over a 24h period based on circadian rhythm modulation.

Figure 6.10 Illustration of the anatomical location of the suprachiasmatic nucleus (SCN) in the anterior part of the hypothalamus.

feedback mechanism (Czeisler et al., 1999; Pace-Schott & Hobson, 2002; Reiter, 2003). This explains why melatonin is effective in shifting the circadian clock.

Genetic and Molecular Correlates of the Circadian Rhythm

The circadian clock is genetically controlled. The underlying genes were first discovered in 1971 in *Drosophila melanogaster*, which has been an essential experimental animal model for both early genetic studies of circadian rhythms and more recent explorations of molecular mechanisms.

The 24-hour schedule driven by environmental input to an internal body clock is made possible by the molecular basis of this clock, which relies on oscillations in the activation or inhibition of particular genes over the span of a day. The key feature of these molecular oscillations is a negative feedback loop in which the protein products of genes actually turn off production of more protein. The negative feedback loop that forms the basis of the molecular clock occurs at the level of gene transcription.

Three alleles of the period genes (called *Per*) were found in mutant flies. One mutant, *Per_s*, has a short (about 19-hour) period of free running; a second mu-

Figure 6.11 Day-by-day plot of sleep and wakefulness pattern illustrating aspects of circadian oscillation. The solid lines indicate sleep and the dotted lines indicate wakefulness during each successive 24-hour period. From day 1 to 9, bedtime is almost identical because circadian oscillations are synchronized by the external environment (effect of daylight on melatonin release). From day 10 to day 34, the subject is isolated from external synchronization (absence of natural light), the circadian oscillation remains but is “free running.” When the external clues are reestablished, the rhythm is synchronized again but shifted.

tant, *Per_L*, has a long (about 29-hour) period of free running; and *Per₀* is arrhythmic. *Per* was later discovered in a lot of different species, including mammals. Mammalian SCN neurons contain three types of period genes (*Per1*, *Per2*, and *Per3*) and two types of cryptochrome genes (*Cry1* and *Cry2*).

The nuclear protein PER is believed to provide negative feedback regulation (Squire & Bloom, 2008). The activated period gene (*Per*) in the nucleus of the cell transcribes messenger RNA (mRNA) molecules. *Per* mRNA moves to the cytoplasm, where ribosomes translate the mRNA into PER. Some PERs degrade shortly after synthesis; others are stable and accumulate in the cytoplasm. Both PER and *Per* mRNA show a circadian oscillation (Squire & Bloom, 2008). The peak in *Per* mRNA precedes that in PER (Squire & Bloom, 2008). PER levels reach a maximum during the middle of the night. At that point, the stable PER enters the nucleus. Inside the nucleus, the PER inhibits transcription of its

own gene. As the sun rises, PER become susceptible to degradation. Over the course of several hours, all PER disappears. In the absence of PER, transcription of the *Per* gene begins again (Figure 6.12).

For the *Per* to be transcribed, two proteins, BMAL1 and CLOCK (positive activators), must bind to a DNA region in the *Per* gene promoter (BMAL1 is the mammalian equivalent of *Drosophila* CYCLE). Transcription results in the production of mRNA, which exits the nucleus through nuclear pores and is translated into protein by the ribosomes. PER molecule, which is susceptible to degradation, forms a dimer with another molecule to increase its stability (homodimer PER/PER or heterodimer PER/CRY). This dimer in turn interacts directly with the complex BMAL1/CLOCK to block activation; therefore PER/CRY dimers act as negative regulators of BMAL1/CLOCK, reducing transcriptional activity of this heterodimer via negative feedback to repress the transcription of their own gene. Dimers PER/PER and PER/

Figure 6.12 Circadian genes. Interaction of four regulatory proteins, entrained by light, creates the daily rhythm of the fruit fly's clock. The binding of CYCLE and CLOCK turns on genes that make PER and TIM, which accumulate over several hours until they reach levels that turn off CYCLE and CLOCK. This, in turn, slows down the production of PER and TIM, which begins the cycle all over again.

CRY degrade over time with photic stimulation, releasing the inhibition on the gene transcription.

Other molecules modulate circadian oscillations. This is the case of the kinase enzyme CK1 ϵ (casein kinase 1 epsilon). This kinase phosphorylates PER protein in the cytoplasm, favoring their instability and degradation, slowing accumulation of PER protein in the nucleus, and thus slowing the rate of inhibition of BMAL1/CLOCK production. It also plays a role in the degradation of the inhibitory complex in the nucleus formed by the heterodimer PER/CRY, boosting transcription. A mutation of the CK1 ϵ protein that makes it less effective in phosphorylating PER results in a wider inhibition of *Per* gene transcription, leading to a shorter circadian rhythm.

This mechanistic alteration is at the basis of human pathologies such that the familial advanced sleep phase syndrome, in which a diminution of efficiency in the phosphorylation process of CK1 ϵ (due to a mutation of the *Per2* gene) leads to a bigger gene transcription of *Per2* and, as a consequence, a shorter sleep cycle.

Though the neural correlates underlying the regulation of the sleep-wake cycle are still being unraveled, it is well established that the reticular formation plays a crucial role in the initiation of both wakefulness and sleep. Sleep onset occurs when the difference between the phases of S and C factors (curves) reach an upper threshold and the environmental milieu (external stimuli) is conducive to sleep. Brain stem and cortical mechanisms of waking are then relaxed: vigilance and consciousness lapse, muscle tone declines, the eyelids close, respiration and heartbeat slow down, and the EEG frequency progressively decreases. However, both thalamus and cortex, unlike the brain stem, are still highly active via the generation of stereotyped thalamo-cortical oscillations during NREM sleep and mentation or dreamlike imagery during REM sleep.

NEURAL SYSTEMS INVOLVED IN AROUSAL AND SLEEP

Sleep is no longer viewed as a passive state (i.e., the absence of wakefulness) but is seen as an active neurobehavioral state that is achieved and maintained by a sophisticated interaction of dedicated neuronal regions in the central nervous system. Here we will review the key elements responsible for the control of sleep and wakefulness.

The pandemic of encephalitis lethargica, which occurred during World War I and over the following decade, led to the first correct prediction about wakeful-

ness- and sleep-promoting regions. This viral infection of the brain resulted in a prolonged sleeplike state of unresponsiveness in most individuals affected. Neurologist von Economo was the first to report the presumed causes following brain autopsy. Prolonged sleepiness was due to lesions in the posterior hypothalamus and rostral midbrain (Saper, Chou, & Scammell, 2001). By observing a subset of patients affected by the same epidemic but showing opposite symptoms of insomnia, he discovered that specific lesions in the preoptic area and basal forebrain were affecting them. Based on his observations, he pioneered the hypothesis of the existence of a sleep-promoting area (neurons located in the hypothalamus near the optic chiasm) and a wakefulness-promoting area (neurons located in the posterior hypothalamus). Subsequent studies have confirmed these predictions. For instance, large posterior hypothalamic lesions produced a prolonged sleeplike state in animals, whereas lesions in the preoptic area/anterior hypothalamus markedly suppressed sleep.

A classic study performed by Moruzzi and Magoun in 1949 demonstrated the existence of an ascending arousal system in the core of the rostral brain stem (brain stem reticular formation) that regulates the level of forebrain wakefulness. Electrical stimulation of this area promotes a waking state. Conversely, transections at a midcollicular level caused an acute loss of wakefulness, and extended damage to this ascending reticular activating system produces a comatose state, followed by a long-term reduction in wakefulness.

Recent studies using modern neuroanatomical tracer methods and immunohistochemistry have revealed the anatomical and pharmacological properties of the reticular formation of the brain stem and the hypothalamus. These systems provide activating inputs to the diencephalon, limbic telencephalon, and neocortex via long axonal projections from localized aggregations of cell bodies (Szymusiak & McGinty, 2008). Several critical nuclei form the reticular formation of the brain stem: noradrenergic neurons (NA) in the locus coeruleus (LC), serotonergic neurons (5-HT) in the dorsal raphe nucleus (DRN), and histaminergic neurons in the tuberomammillary nucleus (TMN).

Cholinergic System

The cholinergic system, which originates in the pedunculopontine and laterodorsal tegmental nuclei (LDT-PPT) of the midbrain reticular formation, is the single most important source of thalamic and hypothalamic innervations (targeting both the thalamic relay nuclei and the reticular nucleus) from the brain stem (Figure 6.13).

Figure 6.13 Monoaminergic anatomical projections.
Ascending arousal system sends projections from the brainstem and hypothalamus to the forebrain.

From "The Sleep Switch: Hypothalamic Control of Sleep and Wakefulness," by C. Saper, T. Chou, & T. Scammell, 2001, *Trends in Neurosciences*, 24(12), p. 727. Copyright ©2001 by Elsevier. Reprinted with permission.

Both of these "activating" nuclei display tonic activation during wakefulness and REM sleep, and significant reductions in activity at sleep onset and during NREM sleep episodes (Szymusiak & McGinty, 2008). They are called REM-on neurons, as they are believed to promote REM sleep by sending excitatory input to the pontine reticular formation. Cholinergic neurons that project from the basal forebrain to the cerebral cortex and limbic areas are part of the vigilance-waking system and are a frequent side-effect target of anticholinergic medications.

Noradrenergic, Serotonergic, and Histaminergic Systems

Noradrenergic, serotonergic, and histaminergic neurons, unlike cholinergic neurons, are nearly shut off during REM sleep (hence their name, REM-off neurons) and act as suppressants of REM sleep by inhibiting REM-promoting cholinergic neurons and by sending inhibitory input to the pontine reticular formation (see Figure 6.13). The noradrenergic wakefulness-promoting system has been found to have an important role in the cognitive function of learning during wakefulness, and activity of this system triggers an increase in the expression of genes associated with memory formation and learning (Pace-Schott & Hobson, 2002). Histamin-

ergic neurons originate from the TMN of the posterior hypothalamus and project diffusely throughout the brain. The neurotransmitter histamine plays a key role in maintenance of vigilance and wakefulness.

Dysfunction of both cholinergic neurons and histaminergic neurons leads to wake and sleep disorders; for example, reduction of histaminergic outputs by anatomical lesions or pharmacological blockade (via antihistaminic drugs that cross the blood-brain barrier, for instance) promotes sleep. Besides their functional implication in waking states, monoaminergic systems are also involved in the pathophysiology of several psychiatric disorders (e.g., depression, post-traumatic stress disorder).

Orexin/Hypocretin System

In 1998, a group of neurons in the lateral hypothalamic area, which express the two neuropeptides orexin 1 and orexin 2 (also called hypocretin), was shown to be critical in wake-sleep regulation and its dysfunction has been linked to narcolepsy (which will be discussed later in this chapter). Patients suffering from narcolepsy experience an inability to maintain vigilance states, with frequent and unwanted transitions between sleep and wakefulness states, and tend to awaken more frequently from sleep as well (Saper et al., 2001). They also experience pathological intrusion of REM sleep during wakefulness, such as loss of muscle tone while awake, a condition known as cataplexy (Saper et al., 2001).

Orexin/hypocretin neurons in the hypothalamus receive abundant input from the SCN (the circadian clock) and from the limbic system (mainly the amygdala) and project all the major systems of the ascending arousal reticular formation (LC, DR, LDT-PPT, and TMN) via excitatory connections (Peyron, et al., 1998; Sutcliffe & de Lecea, 2002;) (Figure 6.14) and therefore are believed to help maintain wakefulness by increasing activity of the ascending arousal system (Saper et al., 2001), and where the mediation of the limbic system might be important for increasing arousal during emotional stimuli (Sakurai, 2007). Concentration of orexin/hypocretin is highest during the waking period. Orexin/hypocretin levels also increase during periods of forced sleep deprivation.

Recent studies report that the effect of orexin on wakefulness is largely mediated by activation of the histaminergic system through orexin receptor type 2 (see Sakurai, 2007). The TMN is believed to be one of the most important effector sites of orexin for the regulation of sleep and wakefulness (Sakurai, 2007). It is, however, important to note that neither orexin knockout animals (animal models that lack orexin neurons

and show phenotypes remarkably similar to those of humans with narcolepsy) nor narcoleptic humans experience excessive amounts of sleep; instead they experience poor maintenance of both wakefulness and sleep, or dysfunctional switching (Saper et al., 2001).

Orexin neurons have also been implicated in feeding behavior and energy expenditure, providing a convincing link between metabolism, food intake, and sleep. Orexin neurons are believed to act as sensors of the nutritional status of the body, as their activity is negatively correlated with changes in blood glucose, leptin, and food intake (Sakurai, 2007). Also, orexin neurons are stimulated by hypoglycemia, which may explain why, when faced with a negative energy balance due to inadequate food availability, mammals respond behaviorally with phases of increased wakefulness and alertness that reinforce food-seeking/feeding pathways (Sakurai, 2007).

Dopamine System

Dopamine acts on the central nervous system (mediated by D1 and D2 receptors), and also via D3 receptors located in the mesolimbic pathways.

The rate of discharge of mesencephalic dopamine neurons is roughly equal through time and does not depend on either wakefulness or sleep stages, which led

to the hypothesis that dopamine signaling may be relevant to regulation of movements of the skeletal muscles and may influence cognitive, emotional, and reward behavior but does not play any direct role in sleep and wakefulness (Siegel & Rogawski, 1988). This view tends to be contested, however, since dopaminergic neurons, along with cholinergic neurons, are continuously active during REM sleep and therefore might have something to do with the peculiarity of REM sleep functions (Gottesmann, 2002).

Melatonin System

Melatonin is a pineal hormone that is known to have a major influence on circadian systems, as well as the endocrine and immune system, along with others. It is also known to exert sedative/hypnotic, anxiolytic, and other neuropharmacological effects.

In humans, the SCN has the highest density of high-affinity melatonin receptors (mostly MT1 and MT2 subtypes) and is synchronized or entrained via these receptors to the environmental light-dark cycle by light (Freedman et al., 1999; Weaver, Stehle, Stopa, & Reppert, 1993).

Melatonin reduces neuronal activity in a time-dependent manner (Cassone, Roberts, & Moore, 1988). The greatest increase in endogenously secreted melatonin by the pineal gland in humans normally synchronized to the environmental light-dark cycle occurs during the early night period. This nocturnal increase in serum melatonin acts as a physiological signal for sleep onset. It has been reported that long-term insomniacs have decreased melatonin levels (Koster-Van Hoffen et al., 1993). Secretion and release of melatonin from the pineal gland are increased by selective serotonin reuptake inhibitor (SSRI) antidepressants and antipsychotic drugs, and inhibited by caffeine, beta-blockers, benzodiazepines, and nonsteroidal anti-inflammatory drugs. The pineal gland acts as a transducer, converting photoperiod signals into chemical signals.

Light exposure can advance or delay the phase of melatonin secretion. In the evening, bright light exposure inhibits and delays melatonin secretion, while darkness in the morning prolongs it, maintaining sleep.

Jet lag, shift work, and increased age are known to affect, disrupt, or weaken the strength of the circadian system. Due to repetitive phase shifts, shift workers internally desynchronize in the long run and consequently tend to have shortened and impaired sleep (Weibel & Brandenberger, 1998). Disruption of the circadian rhythm is observed to an even greater extent in patients suffering from Alzheimer's dementia (Myers & Badia,

6.1

The Impact of the Major Neurotransmitters on Sleep Regulation

NEUROTRANSMITTER TYPE	FACILITATION EFFECT	INHIBITION EFFECT	NONSLEEP-RELATED ACTIONS
Acetylcholine	Wakefulness, REM	—	Motor inhibition during REM
Histamine	Wakefulness	REM	—
Noradrenaline	Wakefulness	REM	Mood and behavior
Serotonin	NREM	REM	Mood, behavior, and motor control
Dopamine	—	—	Cognition, emotions, behavior, and motor control
Melatonin	NREM	—	Circadian rhythm and immune function

1995; Prinz et al., 1984; van Cauter, Plat, Leproult, & Copinschi, 1998).

Neural Mechanisms of REM Sleep

REM sleep is a unique phenomenon that has been identified and defined by Kleitman and Aserinsky in the early 1950s (Aserinsky & Kleitman, 1953). As reviewed earlier, the characteristic features of REM sleep are presence of low voltage fast electrical waves in the cortical EEG, rapid bursts of eye movements in the EOG and atonia in the EMG recorded from postural muscles. REM sleep episodes repeat several times within sleep period and its frequency of occurrence as well as duration per bout increases with the progress in depth of sleep (Kleitman, 1939).

REM sleep is a unique state in the sleep period. Though the mechanism of generation of REM sleep is not fully understood, it is known that during REM sleep epochs, some neurons increase firing (called the REM-on neurons), while others cease firing (the REM-off neurons). Some of the characterizing features of REM sleep, such as cortical desynchronization and eye movement, resemble signs associated with wakefulness, while other signs such as muscle atonia resemble signs associated with sleep. Low activity of noradrenergic and serotonergic neurons is the feature that distinguishes REM sleep most from wakefulness. REM sleep represents the functioning of the cortex without the influence of norepinephrine. The mesencephalic do-

pamine neurons discharge at an equal rate in wakefulness and in all sleep stages (Rotenberg, 2006). Table 6.1 summarizes the impact of the major neurotransmitters on sleep regulation.

REM-On/REM-Off System

REM-on neurons are mostly cholinergic neurons located in the latero-dorsal pedunculo-pontine tegmental (LDT-PPT) areas of the brain stem. REM-off neurons are aminergic neurons located in locus coeruleus (noradrenaline), raphe nucleus (serotonin), and posterior hypothalamus (histamine).

Several investigations performed by the group of Birendra Mallick answered some central questions related to the neural connections between REM-on and REM-off neuron populations for the regulation of REM sleep. They showed that the locus coeruleus (REM-off region) receives a mutually permissive and cooperative inputs of cholinergic and GABAergic systems, controlled by REM-on regions. REM-on neurons may excite the GABAergic neurons, which in turn inhibit the REM-off neurons in LC and generate REM sleep (Mallick, Kaur, & Saxena, 2001; Higo, Ito, Fuchs, & McCarley, 1990; Figure 6.15)

Neural Mechanisms of NREM Sleep

Sleep-promoting neurons are located in the anterior hypothalamus and in the adjacent basal forebrain,

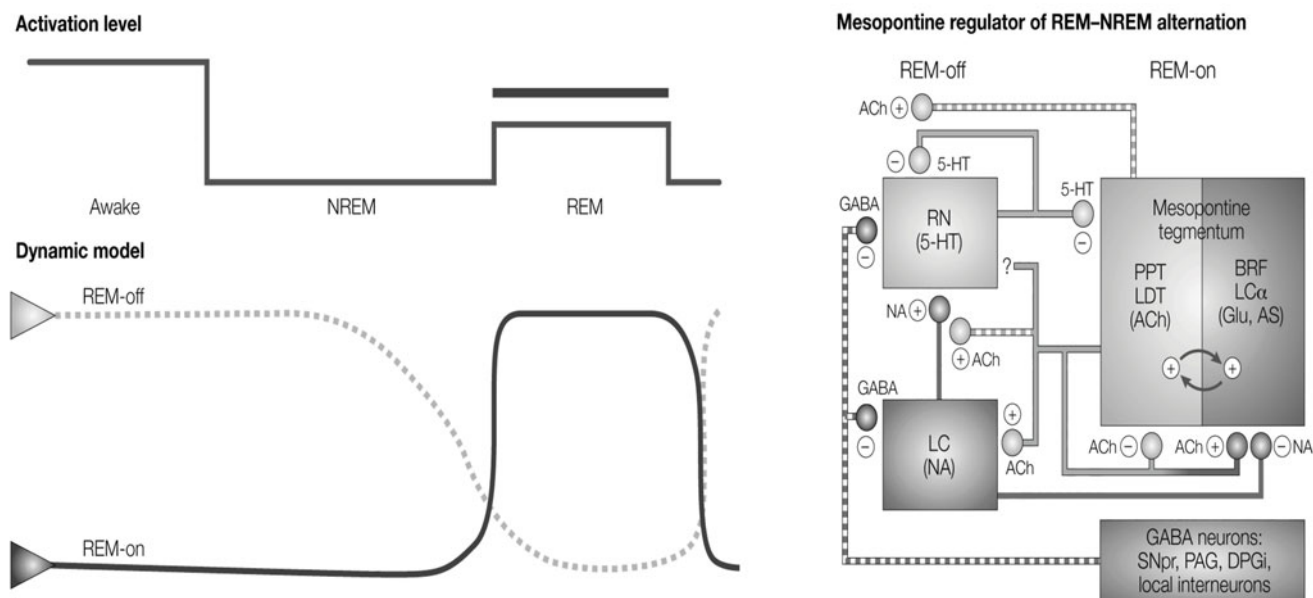

Figure 6.15 Reciprocal-interaction model of REM-NREM alternation. Activation model showing the alternation of REM and NREM sleep states, and the underlying dynamic model of alternating activity of REM-on and REM-off cells in pontine nuclei. specifically in the ventrolateral preoptic nucleus (VLPO; Sherin, Shiromani, McCarley, & Saper, 1996). These neurons discharge maximally during sleep and remain relatively inactive during wakefulness. These regions are under inhibitory control by norepinephrine and serotonin (Chou et al., 2002; Gallopin et al., 2000).

Importantly, sleep-promoting neurons of VLPO send inhibitory projections to the arousal-promoting neurons of the TMN (Lin, Sakai, & Jouvet, 1988; Sherin, Elmquist, Torrealba, & Saper, 1998). VLPO neurons also extend inhibitory projections to all the other wake-active ascending monoaminergic, cholinergic, and orexinergic arousal-promoting regions—that is, the noradrenergic LC, serotonergic dorsal raphe, cholinergic LDT-PPT, and the orexinergic perifornical area PeF and lateral hypothalamic area (Sherin et al., 1998).

A decrease in firing of the NA neurons in the LC of the pons releases the LC's tonic inhibition of GABAergic VLPO neurons, which are in turn activated and release GABA and galanin into LC, TMN, and other arousal-promoting areas. At the level of the LC, this has an inhibitory effect, further decreasing firing in the LC, and therefore further decreasing norepinephrine's tonic inhibition of the VLPO neurons. At the level of the TMN,

descending projections from the VLPO release GABA and galanin. The inhibition by the VLPO of the TMN and the other wake-promoting regions is believed to play a key role in NREM sleep (Figure 6.16). Microlesions of the VLPO in rodents were responsible for insomnia (Lu et al., 2000).

Sleep-Wake Switch

About 80 years ago, von Economo suspected that a rostral hypothalamic area is critical in stabilizing sleep, since damage in this region leads to reduced sleep. Since then, massive experimental evidence has confirmed his hypothesis by demonstrating that the sleep-active ventrolateral preoptic cells interact with wake-promoting areas in the upper brain stem (McGinty & Szymusiak, 2000). Of specific interest is the VLPO region of the hypothalamus, which was identified by Saper through the use of immunohistochemistry (protein immunostaining labeling the gene *c-fos*, which is expressed during sleep). Importantly, most of the VLPO neurons exhibit discharge rates specifically higher during sleep than during waking, and directly proportional to the depth of sleep.

Figure 6.16 Simplified NREM sleep-promoting pathway.

An interesting link exists between this sleep-promoting area and other wakefulness-promoting areas previously described. Indeed, VLPO area sends descending projection to other neuronal population located in the reticular formation (serotonergic, noradrenergic) of the upper brain stem, as well as the TMN (histaminergic), both of which are known to promote wakefulness.

Inhibitory transmitters GABA and galanin are used to mediate these connections—it has been estimated that approximately 80% of sleep-active neurons in the VLPO contain both the GABA-synthesizing enzyme glutamic acid decarboxylase and the peptide galanin (Szymusiak & McGinty, 2008). Even more interesting is the fact that the reticular formation is sending through feedback ascending inhibitory connections to the VLPO, establishing a reciprocal network.

At sleep onset, VLPO neurons are more active (state-dependent activation) and exert a more powerful inhibition on the wake-promoting systems, which in turn relieve inhibition from the reticular formation onto the VLPO. The opposite situation occurs at wake onset, when an arousing input sufficient to stimulate wake-promoting areas results in an inhibition of VLPO areas, thus removing inhibition of wake-promoting neurons. This reciprocal network results in an auto-amplification effect, helping to promote rapid and stable occurrences of sleep or waking phases. In the literature this is referred to as a flip-flop switch or bistable switch.

The preoptic and anterior hypothalamus contain a population of warm-sensitive and cold-sensitive neurons, which are believed to play an important role in thermoregulatory control during sleep. In humans,

sleep propensity is tightly coupled to the circadian temperature rhythm (McGinty & Szymusiak, 2000), and the onset of sleep is normally coupled with a decrease in metabolism, elevation in heat loss, and a fall in body temperature (Szymusiak & McGinty, 2008). Indeed, warm-sensitive neurons show an increase in activity during NREM sleep. Temperature-sensitive neurons could provide a link between sleep and metabolism. Another complementary area in sleep discovered by Szymusiak and McGinty is the median preoptic nucleus (MnPN). MnPN and VLPO share a lot of properties. They both express inhibitory neurotransmitters galanin and GABA and exhibit sleep-active discharge patterns, with even higher discharges during REM sleep. However, it has been shown that MnPN has peak-level discharge early in the development of NREM sleep, whereas VLPO typically displays increased activity in the later portions of NREM sleep episodes. Therefore, MnPN has been hypothesized to be more essential in initiating transitions from waking to stable NREM sleep, while VLPO may predominantly function to maintain sleep stability and continuity (Szymusiak, 2008).

In summary, the neural correlates of sleep onset, NREM, and REM result in a deactivation of aminergic arousal systems mediated through a GABA inhibition originating in the preoptic hypothalamus. On the other hand, monoaminergic activity from the brain stem (noradrenalin and serotonin) during wakefulness prevents inappropriate activation of VLPO neurons.

Reciprocal inhibition between VLPO and the major monoamine areas (TMN, LC, DR) or the ascending reticular arousal system is a key element controlling the switch between sleep and wake states (Saper et al., 2001).

During sleep, the VLPO actively inhibits the ascending reticular arousal nuclei, and during wakefulness these nuclei inhibit actively the VLPO. This reciprocal inhibition uses a “switch” that exhibits two stable states, sleep or wake. The transition between these two stable states occurs infrequently and rapidly, such that the system is never in an intermediate transition state (i.e., situation in between wakefulness and sleep). The transition is therefore ruled by large-scale influences such as circadian drive and homeostatic pressure, provoking a rapid reversal in firing patterns (Saper et al., 2001). This sleep switch can be perturbed in several manners, causing various sleep-wake disorders. On one hand, lesions in the VLPO can weaken the sleep-promoting area and contribute to insomnia with a concomitant increased homeostatic pressure. On the other hand, a destabilizing deficit on the wake-promoting sites induces inappropriate abrupt transi-

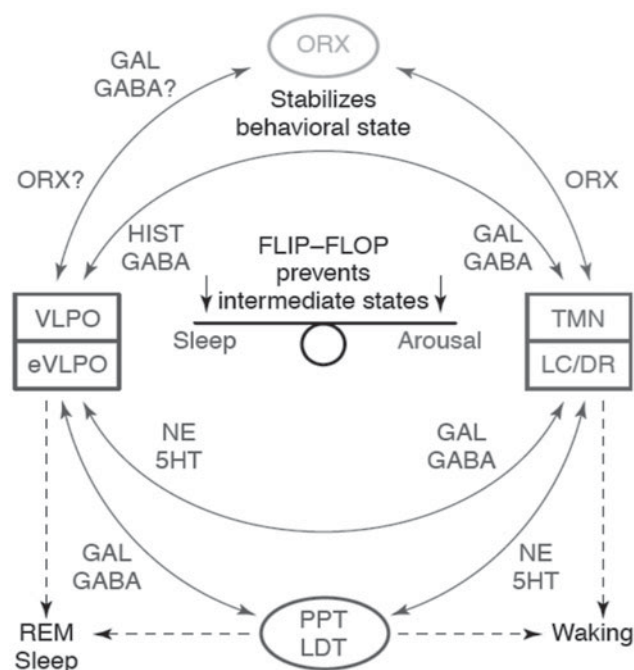

Figure 6.17 Flip-flop mechanism that captures the fast transition between sleep and arousal states, while preventing intermediate vigilance states.

From “The Sleep Switch: Hypothalamic Control of Sleep and Wakefulness,” by C. Saper, T. Chou, & T. Scammell, 2001, *Trends in Neurosciences*, 24(12), p. 729. Copyright ©2001 by Elsevier. Reprinted with permission.

tions from wakefulness to sleep (particularly REM or fragments of REM sleep while awake, such as narcolepsy with cataplexy).

The recently discovered orexin/hypocretin region located in the perifornical area of the lateral hypothalamus is believed to act as a stabilizer in this sleep-wake switch, preventing sudden and inappropriate transitions from wakefulness to sleep. Dysfunction in the orexin region leads to a weakening of the ascending reticular system, disinhibiting the extended VLPO, allowing more frequent transitions into REM, and ultimately leading to narcolepsy. Figure 6.17 summarizes the neural mechanisms underlying this flip-flop switch.

Wakefulness

It is believed that acetylcholine is responsible for the general activation of cortical neurons initiated by the reticular activating system of the brain stem (Kanai & Szerb, 1965). NE and 5-HT in wakefulness are responsible for a partial cortical inhibition. Thus, mental

functioning during the waking state depends upon two types of neurotransmitters: activators, which support the general mobilization of cortical functions, and inhibitors controlling and modulating this activation in order to make mental functions flexible and relevant to the task.

It is believed that during wakefulness the brain stem reticular formation inhibits REM-on neurons and excites REM-off neurons. Midbrain reticular formation wake-related neurons may excite norepinephrinergic REM-off neurons in LC, which then remain active throughout the waking period. The REM-on neurons remain inhibited during wakefulness by the reticular formation. The neurons in the peri-locus coeruleus, which contains the REM-on, are responsible for muscle atonia during REM sleep (Chase, Morales, Boxer, Fung, & Soja, 1986; Morales, Boxer, Fung, & Chase, 1987).

In summary, at the neuronal level, the nuclei in the midbrain reticular formation are active, causing stimulation of REM-off neurons and inhibition of REM-ON neurons, and resulting in absence of REM sleep. REM-off neurons are normally active at all stages (wakefulness and sleep), except during REM sleep, while the REM-on neurons behave in an opposite manner. At the onset of sleep, the activity of the brain stem reticular formation is gradually reduced, progressively diminishing the excitatory and inhibitory effects from the REM-off and REM-on neurons, respectively. Sleep gradually deepens as the wake-promoting neurons progressively cease firing and the sleep-promoting neurons increase firing. The progressive withdrawal of inhibition in REM-on neurons causing their activation and the simultaneous inhibition of REM-off neurons initiate REM sleep. This process is summarized in Figure 6.18.

WHY DO WE SLEEP? SOME FUNCTIONAL THEORIES OF SLEEP

Why would we spend on average one-third of our lives sleeping if it were not for an essential purpose? Sleep can be seen, naively, as counterproductive for humans, and dangerous for animals, since they are the most vulnerable when asleep.

Answering the question “Why do we sleep?” by saying sleep is necessary in order to stay alert and awake is like saying that we need to breathe to avoid suffocation, or eat to keep from being hungry. It does not actually tell us anything about the actual function of breathing, which, for instance, is taking in oxygen and expelling carbon dioxide.

Some experimental observations of the physiological and behavioral changes that result from a lack of sleep have allowed us to infer the essential role of sleep: rats deprived of sleep show weight loss despite greatly increased food consumption (suggesting excessive heat loss) and die in about 2 weeks due to a combination of hypothermia, stress, energy expenditure, failure of host defense (septicemia), and malnutrition (actually faster than if deprived of food). Humans with fatal familial insomnia, an inherited disease that develops in middle age and results in degeneration of the thalamus, usually die within 24 months. Sleep deprivation seems to impair cognitive performance (attention, learning, memory) during the following wake phase. Being sleep deprived while driving or while operating dangerous machines can be even more dangerous than consuming alcohol prior to these tasks. Sleep rebound characterized by a longer and deeper sleep pattern is systematically observed in sleep-deprived people. Finally, a growing body of evidence has linked bad sleep hygiene and problematic pathology such as cardiovascular diseases, obesity, and diabetes.

Sleeping significantly less or more than the average 7–8 hours a night correlates with shorter life spans in humans, and long-term use of sleeping pills is also thought to decrease life span.

Based on these observations, several functional theories about sleep have been hypothesized, some of which appear contradictory at a first glance. The exact role of sleep definitely seems to be one of the most challenging and important discoveries to be made during the 21st century.

It has been proposed that sleep is involved in neuronal plasticity, learning processes, memory consolidation, the coordination of metabolic processes, and the integrity of immune system functioning. Sleep's role in

the promotion of neural plasticity and memory consolidation is the area that has received the greatest interest in the last few years.

The role of sleep in learning and memory is emphasized by studies at behavioral, systems, cellular, and molecular levels (Dang-Vu, Desseilles, Peigneux, & Maquet, 2006). Sleep amounts are reported to increase following a learning task and sleep deprivation impairs task acquisition and consolidation. At the systems level, neurophysiological studies suggest possible mechanisms for the consolidation of memory traces. These imply both thalamocortical and hippocampo-neocortical networks. Concurrently, neuroimaging techniques demonstrated the experience-dependent changes in cerebral activity during sleep. Finally, recent investigations suggest the modulation during sleep of cerebral protein synthesis and expression of genes involves in neuronal plasticity.

Sleep is divided into different constituents, chiefly REM and NREM sleep, and each of these states may convey a different function, and need to be examined individually. The period of life may also have an influence, as reviewed below.

ROLE OF SLEEP DURING NEURAL DEVELOPMENT

Due to the important ratio on the total sleep time that REM sleep occupies during early brain development and the fact that the amount of REM sleep declines to a lower level when the brain development is completed, consequences of REM sleep deprivation during critical periods of brain maturation in animals have been particularly scrutinized.

REM sleep is characterized by a specific phasic activity in the visual system, called the ponto-geniculo-occipital (PGO) waves (Davenne & Adrien, 1987; Mouret, Jeannerod, & Jouvet 1963). Moreover, the release of acetylcholine reaches its nadir during REM sleep, and this neurotransmitter is suspected to influence neural development (Lauder & Schambra, 1999) and synaptic remodeling (Rasmusson, 2000).

Pharmacological manipulation (note page: using for instance the tricyclic antidepressant clomipramine, and the antihypertensive agent clonidine) of chronic REM sleep restriction in neonatal rats led to the (paradoxical) observation of signs of adult depression compared to control groups (Mirmiran, Baldwin, & Ariagno, 2003). Regional brain measurements pointed also to a significant size reduction of the cerebral cortex and brain stem, as well as a proportional reduction of tis-

sue protein in the affected brain areas of the neonatal REM-deprived animal group (Mirmiran et al., 1983). At the neurochemical level, the level of the GABAergic depression of the glutamate-induced single cortical neurons responses was found greater, along with a hypersensitivity of hippocampal pyramidal cells to norepinephrine in REM-deprived animals v. controls (Gorter, Kamphuis, Huisman, Bos, & Mirmiran, 1990; Mirmiran, Dijcks, Bos, Gorter, & Van der Werf, 1990).

Interestingly, REM sleep deprivation for one week induced a decrease in immunoreactivity for the calcium binding protein parvalbumin, which has been demonstrated to influence certain forms of neuronal synaptic plasticity in GABAergic interneurons (Caillard, Moreno, Schwaller, Llano, Celio, & Marty, 2000; Hogan, Roffwarg, & Shaffery, 2001).

Taken collectively, these results suggest that REM sleep deprivation impairs or retards normal brain maturation.

The transition of infancy to childhood and adulthood is characterized by a steep decrease in the total REM sleep time, partially compensated by a sharp increase in NREM sleep time. NREM sleep is also very well characterized by a sleep homeostasis.

NREM sleep is characterized by salient events such as synchronized bursting in thalamocortical structures, transient increases of intracellular calcium, and the release—in some species—of somatotropins (van Cauter & Spiegel, 1999; Steriade & Amzica, 1998). These events may suggest a particular role of NREM sleep in synaptic plasticity. The role of NREM sleep has been particularly emphasized by monocular deprivation studies in cats where it has been suggested an important role for NREM sleep in the rapid cortical synaptic remodeling elicited by monocular deprivation (Frank et al., 2001). NREM sleep seems to be particularly important for the consolidation of visual traces during critical periods of experience-dependent cortical plasticity *in vivo*.

Despite a growing body of evidence suggesting a role for sleep in brain development, little is currently known about the cellular and molecular mechanisms by which sleep exerts its effects.

ROLE OF SLEEP IN LEARNING AND MEMORY IN MATURE BRAINS

From a psychological behavioral perspective, human memory is classically defined as the mental ability to store, retain, and recall information. A memory undergoes at least three major steps in its development: it is initially encoded, then it is consolidated, and finally it

is retrieved. Consolidation can lead to changes, such as either enhancement—that is, a quantitative increase in performance—or stabilization, that is, making the memory less susceptible to interference (Robertson, 2009; Walker, 2005).

In humans, it is, however, misleading to describe a single memory, as memory belongs to multiple systems and can be divided into different types, with some interconnection and independence (Squire, 1992; Tulving, 1987): short-term memory and long-term memory, which can be further divided into declarative memory and procedural memory.

Declarative memory, dealing with memories for facts and events, is constituted of semantic and episodic memories. Semantic memory refers to general knowledge or facts independent of context, while episodic memory corresponds to an autobiographical memory for events that occur in a specific spatial and temporal context. In contrast, procedural memory relates to a learning of skills. Motor learning is part of procedural memory (Cohen & Squire, 1980).

Overlying this classification of declarative and procedural memories is another classification distinguishing between memories that individuals are aware of acquiring (explicit memory) and unaware of acquiring (implicit memory). A common misconception is to relate to declarative memory as being necessarily explicit, and to procedural memory as being implicit. Indeed, these different classifications are not equivalent, but largely independent (Robertson, 2009), since procedural learning can be acquired either consciously or unconsciously (i.e., explicit-procedural or implicit-procedural). Likewise learning a new set of facts though frequently done with awareness (i.e., explicit-declarative), this learning can be acquired unconsciously, i.e. implicit-declarative, such that during subliminal advertising, or priming in a psychology experiment, which may affect our decision making or perception.

A trendy long-lasting hypothesis has been the implication of sleep in the plastic cerebral changes underlying learning and memory in mature brains. It has been postulated that mnemonic traces acquired during a learning experience while conscious would stay in a fragile state until the first post-exposure sleep period has occurred (Fishbein & Gutwein, 1977), the role of sleep being to “consolidate” the mnemonic trace (Maquet, 2001). This concept of consolidation would imply the reactivation, the analysis, and the gradual incorporation of mnemonic traces into long-term memory (Sutherland & McNaughton, 2000).

It is, however, difficult, as of now, to perfectly understand the exact contribution of the different sleep

constituents to memory, because no task can be deemed specific to a single memory system, due to the fact that explicit and implicit contributions to the performance cannot be completely segregated.

Animal and human studies point out modifications in the general architecture of sleep (REM and NREM sleep duration and intensity), which occur in the first of following nights immediately following training or exposure to a learning experience.

Sleep deprivation was found to profoundly interfere with learning and memory consolidation in animals and humans, though it is uneasy to rule out other confounding factors arising from these behavioral studies, such as acute stress response, decreased vigilance, and performance impairments which are known to provoke memory impairment (Horne & McGrath, 1984; Peigneux, Laureys, Delbeuck, & Maquet, 2001).

Declarative learning tasks have been shown to induce both REM and NREM sleep changes. Following training on various learning tasks, animals showed a transient increase in REM sleep duration (Hennevin, Hars, Maho, & Bloch, 1995; Lucero, 1970). The level of performance improvement between practice sessions has been positively correlated with the density of PGO waves (Datta, 2000). A positive correlation between NREM-REM sleep cycles and memorization of word lists has been reported (Mazzoni et al., 1999).

Spindles oscillations detected by EEG, predominant in NREM sleep state 2, have been reported to be potentiated during maze learning paradigm (Meier-Koll, Bussmann, Schmidt, & Neuschwander, 1999), and a positive correlation between their increase and overnight improvement in the number of memorized list of words was observed (Mölle, Eschenko, Gais, Sara, & Born, 2009; Schabus et al., 2004).

However, sleep spindles do not seem to have unique memory enhancement properties. Performance on several declarative tasks has been shown differentially modulated by sleep, depending on the specific sleep stage that is predominant or selectively reduced (Peigneux et al., 2001). Recall of sentences and prose passages is impaired following selective REM sleep deprivation, unlike NREM sleep deprivation (Tilley & Empson, 1978). Conversely, the recall of paired-associate lists of words is better after sleep during the first part of the night, when NREM sleep is predominant, than after sleep during the second half of the night, when REM sleep is predominant (Barrett & Ekstrand, 1972; Fowler, Sullivan, & Ekstrand, 1973). Likewise, the recall of spatial memory in a declarative mental spatial rotation task is better following early than late sleep (Plihal & Born, 1999).

Therefore, it is difficult to pinpoint a particular role of NREM and REM sleep for declarative learning tasks due to the discrepancies observed in these human studies. Importantly, the sole sleep cycle disorganization caused by sleep fragmentation (and not deprivation) during the night was sufficient to cause impairment in the recall of pairs of unrelated words learned the day before (Ficca, Lombardo, Rossi, & Salzarulo, 2000). This suggests that the whole night organization of sleep must be of importance at least for declarative memory.

The same confusion lies also for procedural (non-declarative) tasks, due to several discrepancies between studies about the respective role of NREM and REM sleep. For visual perceptual learning, some investigators reported that selective REM sleep deprivation, but not NREM sleep deprivation, could abolish the overnight performance improvement (Stickgold, James, & Hobson, 2000), while others reported that performance improvement was only altered by early sleep deprivation, dominated by NREM sleep, and unaltered by late sleep deprivation, dominated by REM sleep (Gais, Plihal, Wagner, & Born, 2000). For procedural motor learning, a post-sleep performance enhancement to the rotation adaptation task was positively correlated with a local increase in EEG power in the delta (0.5–4 Hz) frequency range, which constitutes the major electrophysiological marker of SWS (Huber, Ghilardi, Massimini, & Tononi, 2004). NREM Stage 2 spindles have also been implicated in motor learning. A proficiency in learning to tap accurately single finger sequences at an increasingly rapid rate has been reported to positively correlate with stage 2 spindles (Walker, Brakefield, Morgan, Hobson, & Stickgold, 2002).

Of importance is the particular recollection of information associated with an emotional content. Wagner shown that early sleep is overall better for simple declarative memory retention, while REM sleep enhances recall of emotionally charged mnemonic events (Wagner, Gais, & Born, 2001). Indeed, it has been postulated for a while that REM sleep, and possibly REM sleep dreaming in particular, could contribute to the processing of affective memories (Grieser, Greenberg, & Garrison, 1972; Cartwright, Lloyd, Butters, Weiner, McCarthy, & Hancock, J. 1975; McGrath & Cohen, 1978). In psychiatry, shorter sleep latencies and increased REM densities have been linked to major depression (Cartwright, 1983; Kupfer & Foster, 1972), war-related anxiety (Greenberg, Pillard, & Pearlman, 1972), a state of bereavement (Cartwright, 1983), and post-traumatic stress disorder (Ross, Ball, Sullivan, & Caroff, 1989).

Taken collectively, these data demonstrate a role of sleep in memory processing. Almost all the different

sleep stages have been suspected to have a particular role. Yet the results about the specific role of each sleep stage for the different types of memory processes are not univocal and too many discrepancies remain, potentially lying in the different paradigms or investigation care from investigators.

CONTRIBUTION OF NEUROIMAGING APPROACHES IN HUMANS

Reactivation of neural activity patterns during sleep following learning has been observed in various brain areas, across species. It is, however, uneasy in animals to link these neuronal reactivation with subsequent experience-dependent behavioral change. Moreover, due to their invasiveness, classical animal experiments are not transposable to humans.

In the past few decades, functional neuroimaging has emerged as a new way to assess brain function, and has been used both in clinical and research procedures with humans. These methods allow for the quantification of a variety of aspects of brain function, including metabolism, blood flow, and receptor binding. They can provide important information regarding normal brain functioning as well as pathological functions—during sleep for instance—in a way not accessible to traditional polysomnography assessment (Nofzinger, 2005).

Using PET scan, the group led by Maquet showed in 2000 that cortical areas engaged in the implicit acquisition of motor procedural memories are reactivated during post-training REM sleep, but not during NREM sleep (Maquet et al., 2000). The same group showed later that a reactivation of the (para)hippocampal system occurs during post-training NREM sleep, but not REM sleep, following intensive topographical-episodic (spatial) learning in normal human subjects (Peigneux et al., 2004). They also assessed the relation between this experience-dependent reactivation and the modifications in subsequent spatial behavior. By estimating the regional cerebral blood flow with PET technique, they evidenced that the right hippocampus and parahippocampal gyrus are commonly activated during the wakefulness training session and during subsequent SWS at a higher level than in non-trained subjects, suggesting that hippocampal areas that are activated during a spatial learning task are similarly activated during subsequent SWS, which is in line with animal studies pointing out reactivation of neuronal patterns in hippocampal during NREM sleep (Lee & Wilson, 2002; Wilson & McNaughton, 1994). Moreover, they demonstrated a significant correlation between regional cere-

bral blood flow increases observed in these brain areas during SWS compared to wakefulness with a positive overnight gain in behavioral performance from the pre-sleep training to the post-sleep retest session. These neuronal reactivation and increase in regional blood flow may underlie plastic changes leading to a subsequent improvement in performance.

Clearly, NREM and REM sleep seem to be implicated in different type of memory, and the importance of the sequential alternation between NREM and REM sleep stages occurring during the night yet remain to be unraveled.

ELECTROPHYSIOLOGY AND CELLULAR APPROACHES IN HUMANS

Interaction of the Hippocampus and Neocortex

The hippocampus has been shown to be fundamental in memory processes and has been under particular scrutiny for testing sleep-relating memory consolidation hypotheses.

Firing pattern of individual hippocampal cells depends on previous waking experience. Hippocampal neurons activated during a waking period displayed increased activity during subsequent REM and NREM episodes (Pavlides & Winson, 1989). Interestingly, pairs of hippocampal neurons in rodents, whose activity is correlated during a learned behavior are more likely to show correlated activity in NREM sleep subsequent to the training period (Kudrimoti, Barnes, & McNaughton, 1999; Wilson & McNaughton, 1994) and that the temporal sequence of neuronal firing during waking is preserved in subsequent NREM sleep (Skaggs & McNaughton, 1996; Lee & Wilson, 2002). The replay of sequences is not specific to NREM sleep however, and can also be observed during REM sleep (Louie & Wilson, 2001).

Novel mnesic representations seem to be favored compared to the older ones during REM sleep, because hippocampal firing corresponding to new experience during post-exposure REM sleep occurs in phase with the theta rhythm (4–7 Hz), a situation known to favor long-term potentiation, while the firing of hippocampal cells coding for familiar environments tend to be out-of-phase with the theta rhythm, a situation that may lead to depotentiation (Poe, Nitz, McNaughton, & Barnese, 2000).

Hippocampal cells have been shown to exhibit two dominant types of oscillatory patterns (Buzsáki, 1996; Chrobak, Lorincz, & Buzsaki, 2000; Maquet, 2001):

- Gamma (40–100 Hz) and theta (4–7 Hz) oscillations, which are recorded in the superficial layers of the entorhinal cortex, the gyrus dentatus, and the CA3 and CA1 fields of the hippocampus, both during exploratory behavior and REM sleep
- Sharp waves high-frequency ripples (140–200 Hz) initiated in CA3 and recorded in CA1 area of the hippocampus as well as in the deep layers of the entorhinal cortex, during restful wakefulness and NREM sleep

These two major distinct oscillatory pattern, behavior-dependent, led to the elaboration of a two-stage model of hippocampal functioning mediated by hippocampo-neocortical interactions during sleep (Buzsáki, 1989, 1996, and 1998): On the one hand, gamma and theta oscillations would facilitate the transfer of information from the neocortex to the hippocampal areas through the entorhinal cortex. On the other hand, sharp waves and ripples would reverse the flow of hippocampal information and played it back to the neocortex via the entorhinal cortex (Buzsáki, 1996; Chrobak et al., 2000; Siapas & Wilson, 1998). This model might therefore consolidate memory traces, via reactivation and bidirectional pathways.

Putative Role of NREM Sleep Oscillations

NREM sleep oscillations, such as spindles (11–15 Hz), delta rhythm (1–4 Hz), and slow-wave oscillation (< 1 Hz) are believed to have a functional role, yet still to be unraveled. These oscillations are associated with rhythmic spike bursts in thalamic and cortical neurons, which lead to persistent excitability changes (Steriade, 1999). These short-term plasticity processes might be used to consolidate memory traces acquired during wakefulness.

Sleep spindles have received a lot of attention during the last decade, and they have hypothesized to have different—sometimes contradictory—implications. Their functional meaning remains still unclear (de Gennaro & Ferrara, 2003). It has been suggested that spindle activity be related to massive Ca^{2+} -influx into dendrites of spindling cells (Sejnowski & Destexhe, 2000). This massive Ca^{2+} -influx would produce high enough levels of internal calcium concentration $[\text{Ca}^{2+}]_i$ to activate protein kinases and thereby produce LTP. These changes would thus open the gate to subsequent long-term modifications in cortical networks.

Slow-wave oscillation predominant during the deepest stages of NREM sleep (slow-wave sleep) is characterized by widespread synchronization of cortical neurons alternating between phases of hyperpolar-

ization (down-state) and depolarization (up-state), at a frequency inferior to 1 Hz (Steriade, Nunez, & Amzica, 1993). It has been hypothesized that bursting occurring during the depolarization phase would generate short periods of fast oscillations that would iteratively recall and store information embodied in the assemblies primed during spindling (Sejnowski & Destexhe, 2000).

Finally, REM sleep is also characterized by a distinguishing feature, called PGO waves, which can be observed from many parts of the (animal) brain (Hobson, 1964), but most easily recorded in the pons (Jouvet & Courjon, 1959), the lateral geniculate bodies of the thalamus, and the occipital cortex. PGO waves must play a fundamental role in REM sleep, and are suspected to be implicated in central nervous system maturation and potentially neurogenesis. PGO waves might also participate in learning and memory consolidation processes in adults. For instance, PGO wave density between REM sleep episodes was shown proportional to the improvement of task performance between sessions (Datta, 2000). The fact that PGO waves synchronize high-frequency activities (20–50 Hz) led to the suggestion that PGO waves during REM sleep represent a natural physiological process of memory, potentially through the synchronization of fast oscillations that would convey experience-dependent information in thalamocortical and intra-cortical circuits (Amzica & Steriade, 1996). Very interesting, is the temporal relationship of phase-locking observed during PGO waves in REM sleep and hippocampal theta waves (Karashima et al., 2001, 2002), suggesting that interaction between theta and PGO waves has been proposed to be involved in the possible learning and memory functions of REM sleep (Karashima et al., 2004).

It seems that neuronal activity patterns displayed during previous learning session are reinstated during sleep. These reactivations would allow for the adaptation of intercellular connection strengths between the elements of the network and the incorporation of the new experience into long-term memory (Maquet, 2001). Consolidation of memory traces would involve not only the strengthening of some synapses but also the weakening of other, inappropriate, connections that overload cerebral networks (reverse learning; Crick & Mitchison, 1983).

MOLECULAR CORRELATES OF SLEEP AND MEMORY

Studies discussed earlier, relying on neurophysiology, neuroimaging, or psycho-behavioral analyses, can only circumscribed indirectly memory consolidation due to

their systemic level of investigation. Actually, memory consolidation occurs at a very fine molecular level, and consolidation of such traces is known to rely on particular patterns of neuromodulation as well as on gene expression and protein synthesis (McGaugh, 2000).

Importance of Neuromodulation and Neuroendocrine Activity During Sleep

We have already discussed the dramatic changes in neuromodulatory levels occurring during NREM sleep and REM sleep: levels of noradrenaline, serotonin, and acetylcholine decreased during NREM sleep. During REM sleep, noradrenaline and serotonin continue to drop near zero, while acetylcholine increases dramatically to levels comparable or even higher than observed during wakefulness. Due to this peculiarity, acetylcholine has been under particular scrutiny for learning and memory research.

For instance, it has been shown that acetylcholine enhances cortical plasticity in adult mammals (Bakin & Weinberger, 1996; Delacour, Houcine, & Costa, 1990). In contrast, injection of scopolamine, an acetylcholine antagonist, impairs performance on some tasks when administered in rats during REM sleep (Smith & Lapp, 1991).

Acetylcholine seems to play a particular salient role in the two-stage model of memory formation by Buzsáki, discussed in the former section, related to the functioning of the hippocampus-dependent memory system which is believed to be modulated by cholinergic tone changes within the hippocampus across the sleep-wake cycle. Indeed, high levels of acetylcholine would promote the encoding of new information in the hippocampus during wakefulness, by partially suppressing excitatory feedback connections and then facilitating encoding without interference from previously stored information. Conversely, during NREM sleep—and especially SWS—the lower levels of acetylcholine would favor the release of this suppression and therefore allow spontaneously reactivated hippocampal neurons coding for an association to drive cell in the entorhinal cortex and neocortex without any assistance from sensory input, resulting in the facilitation of memory traces consolidation (Hasselmo, 1999; Maquet, 2001).

This hypothesis seems in line with recent studies showing that an increase of cerebral cholinergic activity during SWS sleep, mediated through the injection of a cholinesterase inhibitor in humans, prevented the con-

solidation of declarative memories, but interestingly did neither affect memory consolidation of non-declarative tasks nor alter memory consolidation during waking (Gais & Born, 2004).

The neurotransmitter adenosine, which is seen as a marker of sleep homeostatic pressure, appears also to have a role in learning and memory, at least indirectly by promoting wakefulness and increasing arousal and attention (Fredholm, Battig, Holmen, Nehlig, & Zvartau, 1999).

Glutamatergic transmission may be implicated in sleep-associated consolidation of procedural skills. Administration in human subjects of low doses of caroverine, a fairly selective AMPA receptor blocker, strongly reduced the overnight improvement in some tasks related to procedural memory.

Finally, the hormonal activity and neuroendocrine activity, which is modulated throughout the wake-sleep cycle, seems to also have an implication in learning and memory. During SWS, the activity of the hypothalamopituitary-adrenal system is strongly inhibited, and as a consequence the release of adrenal cortisol is dramatically reduced (Born & Fehm, 1998). High elevated cortisol concentration during SWS resulting from exogenous administration, yielded in the blockade of increase in recall performance for word pairs. This suggests that the spontaneous decrease in cortisol release during early nocturnal sleep might be a prerequisite for the consolidation of declarative memories in the hippocampus, which is a target of cortisol due to its high expression of corticosteroid receptors. As additional evidence, it was shown that glucocorticoid receptors unlike mineralocorticoid have an impact on declarative memory (Plihal & Born, 1999).

DNA/RNA Synthesis During Sleep

Synthesis of DNA and RNA during different vigilance states or following sleep deprivation was carried out by a few investigators (Ambrosini, Sadile, & Gironi Carnevale, 1988; Balestrieri, D'Onofrio, & Giuditta, 1980; Giuditta, Ambrosini, Scaroni, Chiurulla, & Sadile, 1985; Giuditta, Rutigliano, & Vitale-Neugebauer, 1980; Vitale-Neugebauer, Giuditta, Vitale, & Giaquinto, 1970). Two studies performed in rabbits revealed positive correlations between RNA synthesis in neocortical neurons and EEG synchronization during NREM sleep (Giuditta et al., 1980). Results with DNA synthesis were inconsistent and non-replicable as of this writing (Giuditta et al., 1985).

Interpretation of these studies must be done with care because it is currently not possible to link the

evidence of increase RNA following sleep to a sleep-dependent increase in substances involved in synaptic plasticity, since the identity of the mRNA transcripts is still unknown.

These studies are, however, fundamental as they are trying to assess the core of the biological machinery, and should constitute a promising future in the neuroscience of the 21st century.

Gene Transcription During Sleep

Using polymerase chain reaction, a technique used in molecular biology to amplify a single or few copies of a piece of DNA across several orders of magnitude, and microarray technology, Cirelli shown that many genes coding for synaptic plasticity are upregulated during wakefulness or sleep deprivation and down-regulated during sleep (Cirelli, 2002; Cirelli et al., 2004; Tononi & Cirelli, 2001) which would be in line with the synaptic homeostasis hypothesis of sleep.

However, looking more carefully it seems that, on the one hand, the genes which are down-regulated during sleep are mostly genes coding for high energy needs, for instance responsible for high synaptic excitatory neurotransmission, high transcriptional activity, and synaptic potentiation in the acquisition of new information. On the other hand, genes up-regulated during sleep seem primarily involved in membrane trafficking, synthesis and maintenance at different levels, and myelin formation, such as exocytosis and neurotransmitter release and synaptic vesicle recycling.

Interestingly, a gene involved in neuronal plasticity was shown up-regulated during learning post-exposure REM sleep in the cortex and hippocampus of rats, whereas non-exposed rats showed a generalized decrease in the expression of the very same gene both during NREM and REM sleep compared to wakefulness.

Protein Synthesis During Sleep

Besides affecting gene regulation, sleep may also play a role in the translation of these genes into their active proteins. Positive correlations between levels of cerebral protein synthesis and duration of NREM sleep were reported (Nakanishi et al., 1997), supporting the involvement of sleep in protein synthesis, which is believed to be mediated by the inactivity of the noradrenergic system during sleep.

Sleep deprivation also affects directly neurotrophins NGF (nerve growth factor) and BDNF (brain-derived

neurotrophic factor) by reducing their concentration in the cerebellum, brain stem, and hippocampus (Sei, Saitoh, Yamamoto, Morita, & Morita, 2000).

There are currently two major opposing schools of thought, both supported by data: one suggests that consolidation may occur over any time interval, while the other claims that these processes require sleep. The truth might lie somewhere in between.

When a procedural memory (motor skill) and declarative knowledge are acquired simultaneously, sleep seems to be necessary to observe consolidation, as little offline processing is observed during wakefulness. However, when a motor skill is acquired with little or not declarative knowledge, the subsequent offline processing occurs over any time interval, even during wakefulness (Robertson, 2004; Spencer, Sunm, & Ivry, 2006). This implies that declarative learning may compete with motor consolidation over wakefulness.

It is clear that different mechanisms are engaged over wakefulness and sleep. During wakefulness, reciprocal interactions occur between memory systems, while during sleep these systems operate independently (Brown & Robertson, 2007a, 2007b; Robertson, 2009; Robertson, Pascual-Leone, & Press, 2004). Motor learning and declarative learning interfere each other and inhibit each other consolidation during wakefulness only, not during sleep. To consolidate properly, the corresponding offline memory processing may involve not only engaging specific neuroplastic changes, but also disengaging interacting memory systems. This disengagement may lead to an increase of the computational power of memory processing during sleep by getting rid of any possible interferences resulting for memory system interactions (Robertson, 2009). Unlike wakefulness, sleep exhibits this property of disengagement. Sleep may boost the formation of high-order associations that may allow the reconstruction of memories that have been disrupted during prior wakefulness, as evidenced by the ability of sleep to increase insight and reorganize information (Wagner, Gais, Haider, Verleger, & Born, 2004). This disengagement is more likely to be specific to some specific stages of sleep such as NREM sleep, suggested by the fact that during wakefulness and REM sleep, there is a reciprocal dialogue between the hippocampus and cortical areas, whereas a unidirectional pattern of communication from the cortex to the hippocampus appears during NREM sleep (Tononi, Massimini, & Riedner, 2006).

As of now, two major theories conflict with each other on the exact consequence of sleep on memories. The first view (the sleep-related memory consolida-

tion hypothesis) suggests that sleep contributes to increasing the signal associated with a given memory by replaying past experiences (Maquet, 2001). This is supported by numerous of studies, including neuronal activity patterns reactivation during sleep offline time window. It seems that there is a causal relationship between neuronal reactivation and performance improvements. Yet it remains to be seen whether inhibition of these pattern reactivation are correlated with a decrease in performance. The second view, opposing to the first one, is the synaptic homeostasis theory, suggesting that sleep (in particular slow-wave sleep) causes a synaptic downscaling, which would lead to a reduction of the noise associated with a memory. Several experimental sources of evidence also support this hypothesis (Vyazovskiy, Cirelli, Pfister-Genskow, Faraguna, & Tononi, 2008).

Retrieval of memory is influence by many factors, memory consolidation being only one of these. Taken together, these data give the conviction that different memory components are processed during wakefulness and sleep, and that distinct circuits support memory processing during wakefulness and sleep. We hypothesize that these apparent conflicting views and hypotheses may actually correctly describe different processes, which can operate together.

A global framework and unifying view is required to reconcile both theories, which may turn to be both correct.

SLEEP DISORDERS

Due to a rapidly increasing knowledge about sleep in the 20th century, including the discovery of REM sleep and sleep apnea, the medical importance of sleep was recognized. The medical community began paying more attention to primary sleep disorders, as well as the role and quality of sleep in other conditions.

By the 1970s in the United States, clinics and laboratories devoted to the study of sleep and sleep disorders had been founded, and a need for standards arose.

Technically, a sleep disorder (somnipathy) is a medical disorder of the sleep patterns described in the previous sections. The amplitude and the consequences of sleep disorders are striking by the figures associated: more than 60 million Americans are affected by sleep disorders, among more than 40 millions suffering from chronic long-term sleep disorders. Some sleep disorders are serious enough to interfere with our professional lives (work, concentration, productivity) and social

lives via alteration of normal physical, mental, and emotional functioning.

In a recent survey by the National Science Foundation, almost all individuals reporting sleep problems stated that it negatively affected their daily lives. The direct medical associated costs are estimated up to \$16 billion each year. This is, however, the tip of the iceberg as it does not take into account the indirect costs due to loss of productivity and related factors. Sleepiness behind-the-wheel is also estimated to be the greatest factor in car accident, surpassing alcohol and inappropriate speed.

Sleep disturbances are a primary problem. This is highlighted by the fact that the recently introduced *The International Classification of Sleep Disorders* (Association of Sleep Medicine, 2005) lists more than 80 different primary sleep disorders. The understanding and the appropriate management of these conditions is therefore of crucial importance. Most of them can be treated quite effectively. However, a correct diagnosis—if any—is frequently lacking, therefore leaving the problem untreated.

A sleep disorder occurs when one or several physiological mechanisms responsible for initiation of sleep, termination, or establishment in its different various forms, become disorganized, attenuated or exaggerated. These alterations can be summarized in one of the following category:

- (1) Disorders of homeostatic sleep drive (e.g., insomnia or excessive daytime sleepiness)
- (2) Disorders of the ultradian REM sleep rhythm (intrusion of REM sleep fragments during wakefulness such as in narcolepsy)
- (3) Disorders of adaptive drive (e.g., excessive level of arousal for insomniacs)
- (4) Circadian rhythm disorders (e.g., phase-advanced or delayed circadian rhythm due to separation from environmental factors)
- (5) Dissociation of sleep mechanisms (e.g., improper motor inhibition from sleep during wakefulness as in cataplexy and sleep paralysis; intrusion of dream activity into wakefulness)
- (6) Disorders associated with arousal from sleep (e.g., periodic limb movement syndrome and obstructive sleep apnea OSA are responsible for sleep fragmentation)
- (7) Disorders of autonomic and immunological function
- (8) Disorders of motor control (e.g., lack of motor inhibition leading to REM sleep disorder, or upper airway collapse causing central sleep apnea).

Comorbidity and Sleep Disorders

For reasons that we still do not understand, stroke and asthma attacks tend to have a higher prevalence while sleeping. Likewise for some forms of epilepsy, which can appear or generalize during slow-wave sleep, for example, Landau-Kleffner syndrome, which is exacerbated during SWS (Bonjean, Phillips, Dang-Vu, Sepulchre, & Maquet, 2007; Mascetti et al., 2009). Epilepsy is defined as the chronic recurrence of seizures that results from a hypersynchrony and hyperexcitability of neurons. We might therefore understand that the increase of firing synchrony naturally occurring during the deepest stages of SWS can favor the occurrence/resurgence/trigger of epilepsy-like activity. Sleep deprivation can also triggers seizures.

Sleep disturbances can also be a comorbidity factor (i.e., coexist with) of other conditions. When the immune system is particularly solicited due to a pathogen (e.g., the flu), the organism produces cytokines, signaling proteins used for cellular communication, which regulates the duration and intensity of the body's immune response. Cytokines have also powerful sleep-inducing properties, explaining why we feel sleepy or drowsy when infected. This might also be taken in consideration for a person suffering for excessive sleepiness, since he might host a pathogen.

Mental disorders and neurodegenerative diseases are frequently associated with sleep disorders as comorbid factor. Depression causes sleep fragmentation, and increases sleep onset duration. Paradoxically, REM sleep deprivation might be an effective therapy for people with certain types of depression, while it can actually cause depression in other people. Extreme⁴ sleep deprivation leads ultimately to delusional states, hallucinations, extreme irritability, and paranoia.

Parkinson's and Alzheimer's diseases are frequently associated with sleep disorders (excessive sleep, sleep fragmentation, drastic reduction of sleep quality), which can be both caused by the diseases themselves or by side effects of drugs used to control the main symptoms.

Sleep disorders are also a frequent form of paraneoplastic syndromes and can be the starting point of diagnosis of malignancy. Stroke and brain trauma can also induce sleep disorders.

Since a complete dissertation could be written for each of the 80 different sleep disorders, we have decided

to offer a discussion of the major and most salient sleep disorders, such as insomnia and narcolepsy. The important aspect of breathing disorders is devoted to the companion chapter 28. The interested reader will be systematically referred to appropriate textbooks and other references for a deeper and more comprehensive review.

Insomnia and Its Impact

Insomnia (or *agrypnia*) is a symptom of a sleep disorder, usually characterized by repeated difficulties with either initial sleep onset (sleep onset insomnia) or remaining asleep (sleep maintenance insomnia) despite adequate opportunity, condition, and time for sleep.

Patients who complain of insomnia describe their sleep as insufficient or of poor quality, light and easily disrupted, unrefreshing, unsatisfactory, or nonrestorative. Sleep insomnia is diagnosed when at least one of these situations are reported during at least 3 weeks (1) a sleep latency of 30 minutes or more; (2) wake time after sleep onset of 30 minutes or more; (3) sleep efficiency⁵ of less than 85%; (4) a total sleep time less than 6–6.5 hours, at least 3 nights a week. This symptom leads to impairment of daytime function and has direct consequences on cognitive, social, and professional interactions.

Insomnia is the sleep disorder with the highest prevalence and can be caused by a variety of biological, psychological, and social factors. Virtually everyone suffers from it at some stage of his or her life. About 64 million Americans suffer from insomnia on a regular basis each year, and approximately 10%–15% of the population have chronic insomnia. The prevalence increases with age (insomnia is about five times as frequent at 70 years as at 40 years), in women compared to men (ratio 1.4 to 1), in people under particular private or professional pressure (e.g., people with a sedentary lifestyle, shift workers, travelers with jet lag) in addictive substances users (including alcohol), in persons with poor sleep hygiene, and in patients affected by neurological or psychiatric conditions.

Due to a complex combination of factors (lack of training in both diagnosing and managing insomnia, misconceptions about the efficacy and risk of hypnotic medications), insomnia is under-recognized and more than half of the patients do not receive adequate treatment, despite its severity. Without effective therapy, chronic insomnia tends to persist and many patients

4. Cf. World record in sleep deprivation related earlier in the first section.

5. Sleep efficiency is defined as the ratio of sleep time to the total time spent in bed.

report suffering from disturbed sleep for several years. This lack of effective management can result in serious consequences for affected individuals.

It is not surprising to understand the extend of the impact of sleep loss due to insomnia, when we know that chronic restriction of sleep to 6 hours or less per night for 14 nights (short-term partial sleep deprivation) was already found to produce cognitive performance deficits equivalent to as much as 2 nights of total sleep deprivation (van Dongen et al., 2003). Already moderate sleep restriction seriously impairs waking neurobehavioral functions in healthy adults, resulting in a broad spectrum of symptoms impairing daytime functioning (Leger & Poursain, 2005; Morin, 2006), diminishing the quality of daily activities, and the ability to accomplish tasks (Benca, 2005; Ohayon, 2005).

The impact of insomnia is threefold.

Psychological Consequences

- Cognitive impairment (diminished performance, loss of concentration, deterioration of memory, increase of reaction time, and alteration of judgment)
- Decrease productivity
- Alterations in mood, increase in irritability
- Reduced motivation
- Diminished quality of life

Physical Consequences

- Sensation of fatigue and sometimes sleepiness
- Somatic manifestations such as muscle aches (resulting from excessive muscle tension which may cause headaches and neck aches), or gastrointestinal complaints
- Positive correlation with insomnia and chronic pain, hypertension, and diabetes.
- Increased risk of developing psychiatric disorders (e.g., depression, anxiety)

Social Consequences

- Increased likelihood of accidents (at home, while behind the wheel, or in the workplace)
- Decrease of work performance

Life Expectancy

It is well documented that individuals sleeping less than 6 hours per night have a shorter life expectancy than those who report sleeping 7–8 hours per night (people sleeping more than 9 hours per night also have a shorter

life expectancy). This can be explained by diseases underlying sleep disorders on the one hand, or by the fact that insomnia in itself increases morbidity and reduces the rate of recovery from other medical disorders on the other hand. It is documented that both acute short-term partial and total sleep deprivation cause an elevation in high-sensitivity C-reactive protein concentrations (Meier-Ewert et al., 2004), which are a stable marker for inflammation and have been found to be predictive of cardiovascular morbidity.

Types of Insomnia: Classification and Causes

Insomnia can be classified according its duration, its severity, its temporal profile, and its etiology. Insomnia can fall into three different classes according to its duration: (1) transient insomnia if it recurs episodically and infrequently (usually lasting no more than a few days), (2) acute insomnia if it lasts up to 3 to 4 weeks, or (3) chronic insomnia if it persists for more than 1 to 3 months. We can also distinguish insomnia based on its temporal profile in the following three patterns:

- (1) *Sleep onset insomnia*, which consists in difficulty in initiating sleep. It is classically defined as sleep latency greater than 30 minutes and is usually attributed to high level of arousal cause by stress, anxiety, and other factors.
- (2) *Sleep maintenance insomnia*, which is the difficulty in maintaining sleep due to frequent or prolonged awakenings. Awakenings either occur irregularly during the night or at specific times usually during REM.
- (3) *Terminal insomnia*, also called early morning awakening, which corresponds to a final awakening that is earlier than desired. This pattern is the most prevalent among elderly.

It is worth noting than more than 25% of patients suffering from insomnia report a combination of these patterns (Leger & Poursain, 2005).

Finally, insomnia can be also classified based on etiology. On the one hand, primary insomnia is used for idiopathic insomnia unrelated to any comorbid medical disorder, or medication use. On the other hand, comorbid insomnia is an insomnia, which is related to a comorbid medical disorder or medication use. Only 10%–15% of patients with chronic insomnia experience it as a primary condition, therefore not related or caused by any known physical or mental condition.

The remaining 85%–90% experience chronic insomnia in parallel with comorbid medical (physical or mental) conditions (Barkin, 2007; Becker, 2006a; Kupfer & Reynolds, 1997).

Insomnia has numerous and diverse etiologies, and usually several causes or factors are simultaneously present in individuals with insomnia. Spielman, Caruso, and Glovinski (1987) have introduced a model of the genesis and maintenance of insomnia in which they distinguished three categories of factors related to insomnia: (1) predisposing factors (factors increasing the likelihood of insomnia), (2) precipitating factors (factors that trigger the start of insomnia), and (3) perpetuating factors (sustain sleep disturbance and contribute to the persistence of insomnia independent of precipitating causes).

Sleep apneas (central sleep apnea, obstructive sleep apnea, Cheyne-Stokles respiration), disturbances of the circadian sleep-wake rhythm (circadian dysrhythmia), homeostatic deregulation; hyperarousal, restless leg syndrome, periodic limb movement disorder (e.g., nocturnal myoclonus), chronic pain (e.g., back problems),

congestive heart failure, neurological conditions (e.g., Parkinson's and Alzheimer's diseases, or some forms of epilepsy), psychiatric disorders (e.g., depression, mania, dementia), and medication use or withdrawal, all have been associated with insomnia. About 15% of cases of chronic insomnia are attributed to psychophysiologic insomnia, 12% of cases for restless legs syndrome, and 12% for alcohol or drug use and abuse.

Table 6.2 summarizes the main causes known to be related to the three main temporal pattern of insomnia.

Practically, the physician in charge will have to pinpoint the nature of insomnia, its pattern and severity, and identify the plausible underlying etiology. An assessment of the history through a detailed questionnaire is essential, as physical examination is usually of poor information besides evident medical, neurological or psychiatric disorder. Besides a questionnaire, the investigation for a differential diagnosis may also include polysomnography (combined EEG, EMG, EOG, respiratory monitoring), which usually represents a great source of useful information for the specialist and has the advantage to be entirely non-invasive. This technique can

6.2

The Main Causes of the Three Main Temporal Patterns of Insomnia

SLEEP ONSET INSOMNIA (DIFFICULTY INITIATING SLEEP)	SLEEP MAINTENANCE INSOMNIA (DIFFICULTY MAINTAINING SLEEP)	TERMINAL INSOMNIA (EARLY MORNING AWAKENING)
Anxiety	Dementia	Circadian rhythm disorder (advanced sleep phase syndrome)
Circadian rhythm disorder (delayed sleep phase syndrome)	Discomfort	Depression
Drugs	Drugs	Drugs
Hyperarousal	Medical problems (e.g., asthma) or neurological disorders	Mania
Periodic limb movement	Pain	Old age
Poor sleep environment	Periodic limb movement (e.g., nocturnal myoclonus)	Poor sleep environment
Poor sleep hygiene	Sleep apnea	

also be extended to temperature recording, melatonin, and cortisol estimations if circadian dysrhythmia is suspected. Finally, brain imaging (such as computerized tomography, CT, magnetic resonance imaging, MRI, or even fMRI) is a precious and irreplaceable technique to assess brain-stem disorders or other anatomical lesions, or again to assess dementia. Brain imaging has the advantage to be accurate, fast, and non invasive, but its prohibitive associated cost slows down its use on a routine basis.

In the following section, we will review some prevalent etiologies of insomnia. Understanding correctly these etiologies is a prerequisite to developing an efficient therapy.

Inadequate Sleep Hygiene. Inadequate sleep hygiene is believed to be the dominant cause of insomnia. Some factors causing inadequate sleep hygiene include, but are not limited to:

- (1) Sleep environment (e.g., inadequate noise cancellation, temperature, or lightning) and excessive amounts of time spent in bed for non-sleep-related activities (e.g., television watching, telephone conversation, homework).
- (2) Sleep patterns (significant day-to-day variability in bedtimes and rising times, daytime naps)
- (3) Daytime activities (e.g., too little physical activity during the day or excessive and strenuous exercise immediately prior to bedtime; stimulating mental activities performed too close to bedtime; excitement; hunger or heavy meal ingestion too close to bedtime)
- (4) Drugs (e.g., xanthines such as caffeine, theophylline, and theobromine in coffee, tea, and chocolate are stimulants and contribute to a reduction in sleep homeostatic pressure). Alcohol can sometimes precipitate sleep onset but causes sleep pattern disruption and induces poor sleep quality. Other drugs taken for medical purposes such as diuretics and glucocorticoid can also lead to insomnia.

It is important to note that, while being the commonest factor, inadequate sleep hygiene remains mostly a precipitating factor, which needs to be combined with one of other precipitating, or predisposing factors in order to observe insomnia.

Hyperarousal States. Hyperarousal states are thought to be the second most prevalent causes of chronic insomnia (Bonnet & Arand, 1997). This represents an exag-

geration of the normal adaptive drive during wakefulness, which allows alertness to continue even when the circadian and homeostatic regulators should promote sleep.

A faster heart rate during sleep of insomniac patients compared to normal subjects is observed, probably mediated via an increased sympathetic activity. At the neuronal level, a hyperarousal state characterized by a low threshold for arousal from internal or external stimuli may represent a failure of the thalamocortical projections to modify the activity of the cerebral cortex in the usual way during sleep. Anxiety states, post-traumatic disorders, chronic fatigue syndrome, fibromyalgia, and anorexia nervosa are some examples of clinical manifestations of hyperarousal states.

Circadian Rhythm Disorders. Circadian rhythm is a key element in the regulation of sleep and determines the threshold of the homeostatic and adaptive drives to initiate sleep. Therefore, disturbances or desynchronization in circadian rhythms can cause several sleep disorders, including insomnia. Several causes of disturbance are reported, whether it is caused by endogenous or exogenous factors.

Endogenous factors are closely linked to neurological disorders. Head injuries, degenerative disorders, and tumors can all disorganize sleep controls by damages to the circadian mechanism. Blindness and damage to the retinohypothalamic tract lead to the alteration of circadian rhythms because external “time givers,” particularly light, is reduced or absent. Exogenous factors are more related to the imposition of changes in the environment, which may affect circadian rhythms. It may be due to social factors, jet lag, or shift work, mostly causing change in the exposure to light which leads to melatonin concentration shifts, and *ipso facto* in alterations in sleeping times. Light therapy is usually the best treatment.

Neurological Disorders. The brain stem, hypothalamus, and thalamus are key regions controlling sleep and wakefulness. Lesions in these areas in consequence of neurological disorders can induce, in some cases, insomnia.

Tumors in the anterior hypothalamus and thalamic infarction cause frequently insomnia. Fatal familial insomnia, which is an extremely rare disease characterized by degeneration in the dorsomedial and anterior thalamic nuclei, due to a genetic mutation in the prion protein gene of the brain, leads to inability to initiate and maintain sleep. The patients observe a progression

into complete sleeplessness, which is untreatable and ultimately fatal.

Creutzfeldt-Jakob disease, which is also an incurable prion disease, affects predominantly the cerebral cortex, and in a subtype, also causes an extensive thalamic atrophy. Besides progressive dementia, memory loss, motor abnormalities, and hallucinations, insomnia is a prominent feature where NREM and REM sleep are progressively lost. This disease is fatal.

Dementia due to degenerative disorders such as Alzheimer's disease exacerbates the effect of insomnia, already common in the elderly. Patients with such disorders are affected by a loss of the sleep-wake cycle and of the normal sleep architecture. Nocturnal restlessness, agitation, confusion, and frequent awakenings and wanderings occur. These abnormalities usually worsen with a diminution of exposure to light (such as in winter).

Traumatic brain injury, movement disorders, and periodic limb movements may also cause insomnia.

Psychiatric Disorders. Insomnia is a common and occasionally the initial symptom of depression. Changes in circadian rhythms such as cortisol secretion are common in depression and a reduction in melatonin secretion may contribute to early morning awakening.

Manic phase observed in bipolar patients causes sleep restriction and is usually accompanied by significant alteration in the sleep architecture. Mood swing and changes in the diurnal cortisol secretion pattern are frequent. Excessive daytime sleepiness occurs with the depressive phase of bipolar disorder, once the manic phase is over.

Patients with obsessive-compulsive disorders frequently report insomnia due to compulsive rituals they need to perform.

Schizophrenic patients often complain of insomnia, mostly during acute exacerbations.

Other Medical Conditions. Respiratory disorders such as obstructive and central sleep apneas may cause insomnia. More frequently, however, they cause excessive daytime sleepiness due to a drop in the sleep quality index.

Metabolic disorders, such as chronic renal failure and nocturia may lead to insomnia. Finally, endocrine disorders also leads to insomnia. This is the case for diabetes mellitus, Cushing's syndrome, premenstrual period, pregnancy, and menopause.

Neurophysiological Correlates of Primary Insomnia. A recent study published in *Sleep* showed that people with

primary insomnia for more than 6 months have 30% less GABA (Winkelman et al., 2008). Reduction of GABA in the brain of individuals with insomnia suggests that overactivity is present not only at the level of excessive thoughts and emotions, but can also be detected at the level of the nervous system. This recent finding tends to confirm that primary insomnia (i.e., occurring without the conjunction of another illness or disorder) is a manifestation of hyperarousal. Lower-brain GABAergic levels is also found in patients suffering of major depressive disorder and anxiety disorders. It is therefore meaningful to suggest that mood and anxiety disorders may be tied to sleep disturbances. As we will show in the next section related to treatment of insomnia, pharmacological drugs potentiating GABA activity have been used extensively to treat insomnia.

Treatment of Insomnia

At least 25% of American adults have reported using sleep aids, including about 9% using over-the-counter medications and 7% using prescription sleep aids (Buscemi et al. 2005; Sateia, Doghramji, Hauri, & Morin, 2000).

Despite evidence of major harm and little evidence of clinically meaningful benefit, prescriptions for benzodiazepines continue to grow and are on a list of the top 20 prescribed drugs (Wagner et al., 2004). Moreover, use of benzodiazepines for treating insomnia is usually associated with poor functional status, cognitive impairment, daytime sleepiness, falls, and depressed mood (Busto, Sproule, Knight, & Herrmann, 2001; Hogan, Maxwell, Fung, & Ebly, 2003; Simon & VonKorff, 1997).

Moreover, some commonly used drugs are well known to disrupt normal sleep—notably alcohol, selective serotonin reuptake inhibitors (SSRIs, antidepressants), drugs for Parkinson's disease, methyxanthines (e.g., caffeine), and diuretics—and should be considered as potential facilitators to insomnia.

The treatment approach for a sleep disorder should be threefold: (1) remove or mitigate the underlying problems, (2) prevent the progression of transient to chronic sleep disorder, and (3) improve the patient's quality of life (Kupfer & Reynolds, 1997). To this end, several treatment options are offered to the primary care providers. As we will conclude, the choice of an effective treatment is context-dependent and a wise approach consists usually in a combination of treatments due to multiple underlying causes contributing to insomnia.

Pharmacological Therapy. So-called sleeping pills have become a lucrative business and the variety of different pharmacological agents gives us an indication of the spread on the market. We can find complementary and alternative treatments, over-the-counter medications, and FDA-approved medications. So far, efficacy has been demonstrated only for the FDA-approved insomnia treatment medications, and significant safety concerns exist with many of the medications used on an off-label basis and with selected over-the counter and unregulated substances (Lieberman & Neubauer, 2007).

Over the centuries, many different sleep aids have been tried, with highly variable efficacy and outcomes. Fortunately, the constant increase knowledge of neurophysiological mechanisms regulating wake and sleep allowed us to witness recently the development of targeted, safer, and more efficient pharmacotherapeutic options.

Alternative Treatments and Over-the-Counter Medication. The profusion of various drugs, the readily availability of over-the-counter medications, and the intoxication by unregulated commercials push people to self-medicate instead of seeking appropriate clinical help. A review by the National Institutes of Health in 2005 showed that the use of complementary and alternative pharmaceutical approaches to treat insomnia is considerable in the United States (National Institutes of Health, 2005). Due to major safety concerns as well as the lack of demonstration of the effectiveness of the alternative medication, the National Institutes of Health did not endorse any of these substances for treating insomnia. Over-the-counter drugs sleep promoters (usually sedative antihistamines such as diphenhydramine), and herbal medications (such as Valerian) have limited evidence establishing their effectiveness and are usually associated with hepatotoxicity. Antihistaminics produce a poor quality of sleep, daytime sleepiness, and cognitive impairment.

Melatonin, a naturally occurring hormone produced by the pineal gland in humans, is a key regulator of circadian rhythms. Body production of melatonin peaks with darkness and facilitates induction of sleep. Disruption of the production of melatonin or mismatch of the hormone peak with bedtime cause circadian dysrhythmia and sleep disturbances. It is usually what is happening with work shifts and jet lag. In the United States, melatonin oral supplement are available as over-the-counter drugs in the form of herbal medication or food supplement. While these supplements may have some sort of efficacy for transient circadian dysrhythmia

(during a transatlantic flight for instance), use of melatonin hormone supplement has not been demonstrated being efficient in treating insomnia (National Institutes of Health, 2005). Short-use is usually considered as safe, but no long-term use data exist on its safety. The FDA does not regulate this product.

Off-Label Use of Regulated Drugs. Antidepressant drugs are been heavily prescribed to treat insomnia, despite the absence of a FDA indication and that the National Institutes of Health does not recommend the use of psychiatric medications to treat symptoms of insomnia. Three antidepressant drugs rank among the top 4 prescribed medication to treat insomnia, and only 4 of the top 16 drugs prescribed in this context are FDA approved for insomnia, as shown by a study realized in 2002 (Walsh, 2004).

As reviewed in the first section about neural correlates of sleep, adrenergic, histaminergic, cholinergic, and dopaminergic systems in brain stem midbrain and basal forebrain have been implicated in the promotion and maintenance of wakefulness in the arousal systems of the brain. Antagonizing these systems, like antidepressant and antipsychotic medications do, may induce or promote sleep. However, the classical error in logic with untrained physicians is to believe that medication promoting sleep is ipso facto fitted to treat insomnia.

Though their neural mechanisms are still mostly elusive, antidepressant medications are known to have a large amount of adverse side effects, including sedation, dizziness, xerostomia (dry mouth), dehydration, constipation, psychomotor impairment, priapism, and cardiovascular problems (e.g., tachycardia, orthostatic hypotension). Nevertheless, in spite of the lack of data assessing their efficacy in the treatment of primary sleep disorders, antidepressants are leader in the insomnia prescription trend in the United States. Alone, trazodone represents more than 22 % of the share (Buscemi et al., 2005).

Trazodone (Desyrel) is one of the most commonly prescribed agents for treating insomnia (Mendelson, 2005; Nierenberg, Adler, Peselow, Zornberg, & Rosenthal, 1994). Unlike most antidepressants of the new generation antidepressants, such as fluoxetine (Prozac), trazodone is neither a serotonin reuptake inhibitor nor a monoamine oxidase inhibitor, but acts as an antagonist at both serotonin 5HT-2A and 5HT-2C receptors, histamine-1 receptor, and alpha-1 adrenoceptors (Curry, Eisenstein, & Walsh, 2006; Sharpley & Cowen, 1995; Owens, Morgan, Plott, & Nemeroff, 1997). It has also been reported that trazodone inhibits recombinant

low-voltage-activated T-type calcium channels (Kraus, Li, Jovanovska, & Renger 2007). Another popular insomnia prescriptions are the antidepressants amitriptyline and mirtazapine (Remeron). Amitriptyline is a tricyclic antidepressant with a wide range of pharmacological actions. It acts primarily as a non-selective serotonin and noradrenaline reuptake inhibitor, therefore increasing the concentration of noradrenaline and serotonin at the receptor site. Amitriptyline has also some affinity for the muscarinic, adrenergic, and histaminergic systems (Guaiana, Barbui, & Hotopf, 2007). Mirtazapine is an antidepressant that blocks presynaptic NA α -2 adrenoceptors, and antagonizes 5-HT_{2A}, 5-HT_{2C}, and 5-HT₃ receptors (Davis & Barkin, 1999). Clinically, mirtazapine has a sedating profile, which is probably due to H₁ histamine receptor blockade at low doses (Arnone, Horder, Cowen, & Harmer, 2009).

Quetiapine (Seroquel and Ketipinor) and olanzapine (Zyprexa and Olzapin) belong to the family of atypical antipsychotic, used in the management of schizophrenia and bipolar I disorder. They are also used despite the absence of FDA indications for the treatment of insomnia. They are classified as thienobenzodiazepines and have a high antagonist affinity for 5HT-2c receptors. They have also antagonist activity with α -adrenergic, cholinergic muscarinic, and histamine receptors (Green, 1999a, 1999b; Sacher et al., 2007).

However, no studies have demonstrated the effectiveness and safety of antidepressants and antipsychotics for treatment of patients with chronic insomnia who have no psychiatric comorbidity, and therefore should be taken with caution (see Table 6.3).

FDA-Approved Medications. The only FDA-approved medications indicated for the treatment of insomnia are the hypnotic benzodiazepines, the hypnotic non-benzodiazepines GABA agonist, and the melatonin receptor agonist ramelteon (Rozerem).

In the 1950s and 1960s, chloral hydrate and barbiturates were used for their sedative properties. Major concerns about widespread abuse and lethal overdoses lead to the development of benzodiazepines in the 1970s. For several decades, benzodiazepine receptor agonist (BZRA) hypnotic medications were the only medications approved by the FDA for the treatment of insomnia, and represented a major step forward compared to chloral hydrate and barbiturates.

However, they were associated to potential abuse, major side effects. Association with road traffic accidents and increased falls in the elderly were reported. Prolonged consumption of benzodiazepines causes dependence and withdrawal shows classical of GABAergic

withdrawal symptoms such as initial insomnia followed by a prolonged period of anxiety and agitation.

Introduced in the early 1990s, non-benzodiazepine hypnotic agents were shown to be as effective as the former hypnotic benzodiazepines, with a reduced side-effect pattern and a lower potential abuse, which gave them an immediate popularity and became by far the most widely prescribed hypnotics. These newer hypnotic agents, zolpidem, zopiclone, and zaleplon, act as agonists at the benzodiazepines receptor component of the GABA complex. They are rapidly absorbed orally, have an excellent side-effect profile and have a low interaction potential (Wagner & Wagner, 2000). Zaleplon has an ultra-short half-life, which makes it useful for promoting sleep even if taken during the night (Israel & Kramer, 2002). Zolpidem, with a longer half-life, not only shortens sleep latency but also promotes sleep maintenance. Zopiclone has a slightly longer half-life and thus greater potential for sleepiness following day.

BZRAs—which include both benzodiazepines and non-benzodiazepines—are believed to have a direct effect on the homeostatic regulation of sleep. Homeostatic control of the sleep-wake cycle involves separate arousal sleep mechanisms, with VLPO inhibiting by GABAergic contacts the arousal neuronal systems (Möhler, 2006a, 2006b). Decreased inhibition of the arousal system, resulting from GABAergic deficit, has been linked to chronic insomnia and a decrease of SWS. BZRAs allosterically modulate GABA channels to facilitate the action of GABA, therefore increasing the flow of chloride current into the neuronal membrane and hyperpolarizing the neuron.

Unlike barbiturates, which directly activate GABA channels, BZRAs have a safer profile because they depend on presynaptic release of GABA (Goodman & Gilman, 1990). Non-benzodiazepines bind selectively to GABA-A receptors (mostly subtype A₁) linked to sedation, while benzodiazepines also bind to other non-sleep-mediating receptor subtypes, inducing wider spectrum of non-sleep related pharmacological effects (Goodman & Gilman, 1990; Neubauer, 2006).

Benzodiazepines decrease sleep latency and increase total sleep time but also alter dramatically the sleep architecture, increasing the time spent in stage II, while decreasing time spent in deep sleep (stage III) (Borja & Daniel, 2006; Goodman & Gilman, 1990). Benzodiazepines also shorten REM sleep but increase NREM-REM sleep cycles (Borja & Daniel, 2006). Non-benzodiazepines, because of their higher affinity to GABA-A₁ receptors, minimally disrupt sleep architecture, while reducing sleep latency and slightly increasing total sleep time.

6.3

Common Medications Used for Insomnia Without FDA Indication

DRUG NAME (GENERIC)	BRAND NAME	ESTIMATED CONCENTRATION (mg)	METABOLISM	ELIMINATION HALF-LIFE (h)	LEGAL STATUS
ANTIDEPRESSANTS					
Amitriptyline	Elavil	25–50	Hepatic/Renal	12–24	Unscheduled
Doxepin	Aponal	25–150	Hepatic/Renal	10–30	Rx only
Trazodone	Desyrel	50–150	Hepatic/Renal	3–6	Rx only Unscheduled
ANTI-HISTAMINES					
Diphenhydramine	Benadryl	50–100	Hepatic (CYP450)	6–8	Over the counter Non-regulated
Doxylamine	NyQuil Somnil Restavit	6.25–25	Hepatic	6–12	Over the counter
Hydroxyzine	Vistaril Atarax	25–50	Renal	20–25	Rx only
ANTI-PSYCHOTICS					
Olanzapine	Zyprexa	2.5–5	Hepatic (glucuronidation, CYP1A2,2D6)	21–54	Rx only
Quetiapine	Seroquel Ketipinor	25–50	Hepatic (sulfoxidation, CYP3A4)	6–7	Rx only
OVER THE COUNTER (UNREGULATED)					
Melatonin	SleepMD	1–10	Hepatic (CYP1A2)	0.5–1	Unregulated Untested
Valerian		400–900	Not established	Not established	Unregulated Untested

All these drugs are recommended to use for between two and four weeks. Despite this, chronic usage is not uncommon in clinical practice, though the abuse potential is not completely absent for non-benzodiazepines. Benzodiazepines such as temazepam are also effective in short-term use but require even more careful monitoring due to a greater potential for causing morning sedation, memory dysfunction, dependence, abuse, and withdrawal effects.

Alternative strategies for the long-term treatment of chronic insomnia are certainly needed. While BZRAs interact with the homeostatic regulation of sleep, ramelteon has a totally novel mechanism of action by acting directly with the circadian arousal signal and reset the circadian pacemaker in the suprachiasmatic nucleus (SCN). Ramelteon is the first using this new mechanism of action to be approved by the FDA in July 2005 for the treatment of insomnia. Unlike other melatonergic agonists, ramelteon enhances sleep onset by acting as a specific melatonin MT1 and MT2 receptor agonist, without any known significant interference with other receptor systems (Pandi-Perumal, et al., 2007). Ramelteon has no relevant affinity for the GABA receptor complex, or for any other receptor that binds dopamine, norepinephrine, acetylcholine, opiates or neuropeptides, and has a very low affinity for the serotonin 5-HT-1A-receptor. As reviewed in the precedent section about normal regulation of sleep and wake, melatonin has some physiologically important chronobiological effects—including sleep-promoting effects—mediated via specific melatonin receptors located in the suprachiasmatic nucleus (circadian pacemaker). These effects are distinct from those that result from the introduction of supraphysiological amounts of melatonin from exogenous sources—like from over-the-counter melatonin supplements, some of which are not receptor-mediated and involve metabolism, either in terms of formation of new bioactive compounds or interactions with free radicals (Pandi-Perumal, et al., 2007; Reiter, 2003; Pandi-Perumal, 2006). Unlike over-the-counter melatonin supplements which have not received approval from the FDA and for which inconsistent results have been reported (some investigators reporting an absence of effects on sleep latency; Buscemi, et al., 2006; van den Heuvel, Ferguson, Sally, Macchi, & Dawson, 2005), ramelteon has been proven efficient to induce sleep initiation and maintenance, as demonstrated in animal models and human clinical trials. Ramelteon is assumed to promote sleep efficacy mostly by influencing chronobiotic sleep regulation and seems efficient in treating transient and chronic insomnia, without causing addiction, hangover, with-

drawal effects, or rebound insomnia with discontinuation of the treatment unlike benzodiazepines (Roth, Stubbs, & Walsh, 2005; Roth et al., 2006).

When given 30 minutes prior habitual bedtime, ramelteon was reported to significantly reduce sleep latency by 13 minutes (group of middle-age patients with insomnia) up to 29 minutes (group of elderly patients with insomnia). Increase in total sleep time was also reported. These effects were demonstrated from the first week onwards, and became increasingly more pronounced until the end of the study (week 5).

Ramelteon, administered orally a few minutes prior to usual bedtime, is rapidly absorbed at a rate of at least 84% by the body and reaches peak serum concentrations within 0.5–1.5 hours. Due to its molecular structure, ramelteon has a greater lipophilicity and consequently superior penetration and absorption into tissue compared to melatonin. Also, its half-life is about of 1–2 hours, which is considerably longer than that of melatonin, and therefore better indicated for sleep maintenance. Ramelteon is also eliminated at a sufficient rate to avoid accumulation.

The safety of ramelteon is similar to that of placebo in all doses studies (Cajochen, 2005; Erman, Seiden, Zammit, Sainati, & Zhang, 2006). During short-term administration, ramelteon seems to be well tolerated. Long-term treatment requires further study. Because of its route of metabolism, ramelteon is counter-indicated with the antidepressants fluvoxamine, antibiotic ciprofloxacin, and antiarrhythmic mexiletine, among other (Wurtman, 2008). Table 6.4 summarizes the classical FDA-approved medications for the treatment of insomnia.

A delicate problem arises with chronic insomnia that may require a long-term treatment, therefore being uneasily approached by the use of classical sedatives and hypnotics being limited to short-term use (meaning 2–4 weeks). Nonpharmacological treatment should therefore be combined with short-term hypnotic use. The prescription of hypnotics without attention to other lifestyle changes will rarely result in a satisfactory outcome. Data point the particular safety and efficacy of the new drug ramelteon (Rozerem) in treating narcolepsy.

Nonpharmacological Therapy. As reviewed above, long-term use of pharmacological agents is to be taken with caution. Hypnotics have a high potential risk of tolerance, dependency, and rebound insomnia on withdrawal (Mendelson, et al., 2004). Though newer non-benzodiazepines hypnotics are less likely to lose efficacy over time, they share with other sleeping pills a significant potential to foster psychological dependence (Yang, Spielman, & Glovinsky, 2006).

6.4

FDA-Approved Medication for the Treatment of Insomnia

DRUG NAME (GENERIC)	BRAND NAME	ESTIMATED CONCENTRATION (mg)	METABOLISM	ELIMINATION HALF-LIFE (h)	LEGAL STATUS
BENZODIAZEPINES					
Estazolam	ProSom	1–2	Hepatic	10–24	Schedule IV
Flurazepam	Dalmane	15–30	Hepatic	40–250	Schedule IV
Quazepam	Doral	15	Hepatic	39	Schedule IV
Temazepam	Restoril	7.5–30	Hepatic	8–20	Schedule IV
Triazolam	Halcion	0.125–0.25	Hepatic	1.5–5.5	Schedule IV
NON-BENZODIAZEPINES					
<i>Imidazopyridine:</i>					
Zolpidem	Ambien	5–10	Hepatic (CYP3A4)	2–2.6	Schedule IV
Zolpidem-ER	Ambien CR	6.25–12.5	Hepatic	2.8	Schedule IV
<i>Pyrazolopyrimidine:</i>					
Zaleplon	Sonata	5–20	Hepatic	1	Schedule IV
<i>Pyrrolopyrazine:</i>					
Eszopiclone	Lunesta	1–3	Hepatic (CYP3A4 and CYP2E1)	6	Schedule IV
MELATONIN RECEPTOR AGONIST					
Ramelteon	Rozerem	8	Hepatic (CYP1A2)	1–2.6	Rx only

The need to investigate alternatives to pharmacological treatments has shown that non-drug treatments are at least as effective as pharmacological ones, regardless of whether the origin of insomnia is primary or secondary to medical disorders (Krakow, et al., 2001; Morin, Culbert, & Schwartz, 1994; Morin, Colecchi, Sood, & Brink, 1999; Morin, Hauri, et al., 1999; Smith, et al., 2002).

A conceptual model including psychological and behavioral factors influencing the neurophysiologic regulation of normal sleep is illustrated in Figure 6.19.

Sleep Cognition. In some cases, insomnia is directly associated with stressful or traumatic events. After several nights of poor sleep, anticipation of the daytime consequences of sleeplessness produces a state of

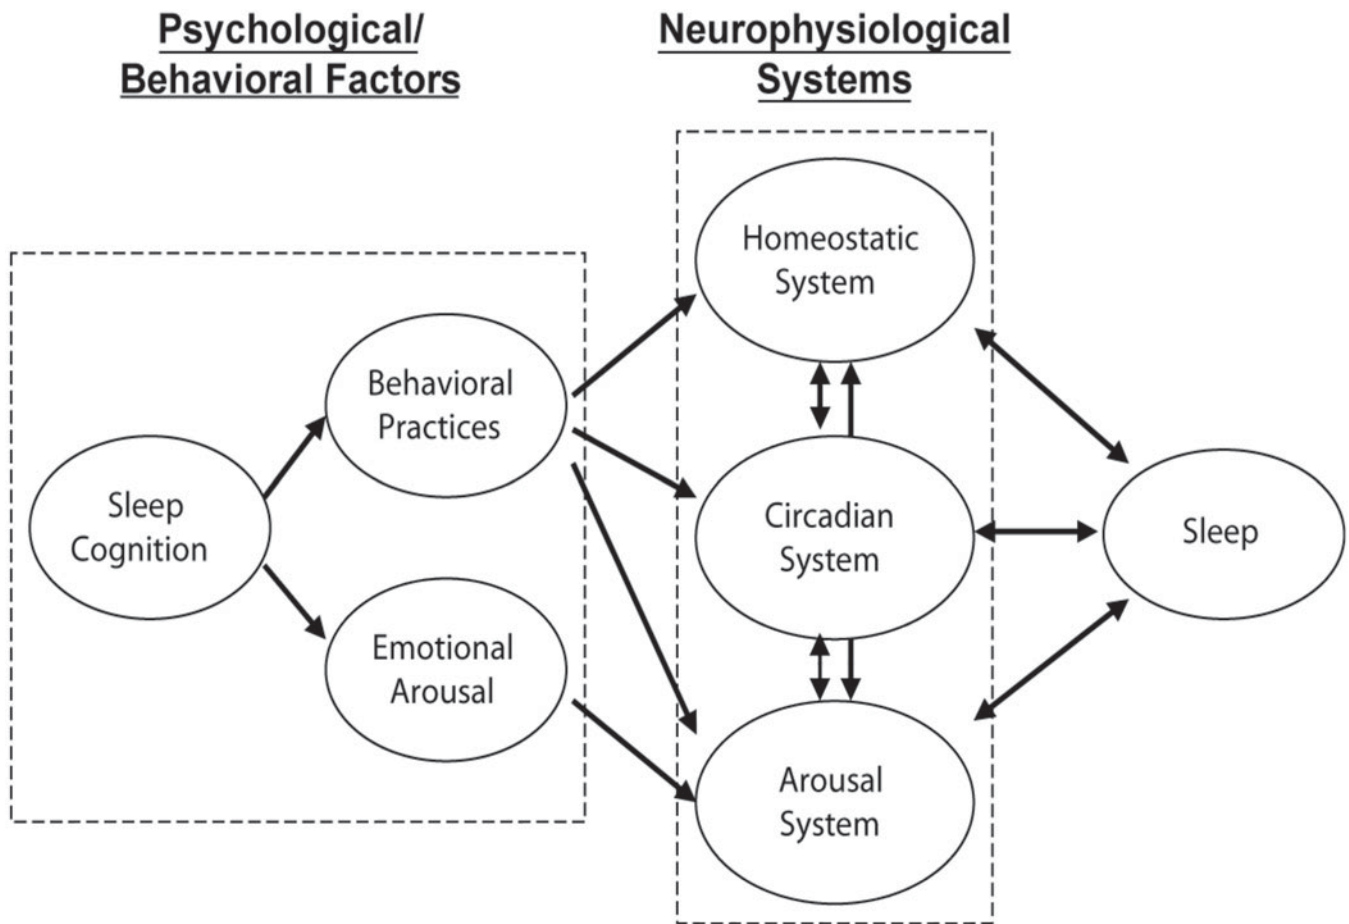

Figure 6.19 Conceptual model of behavioral and psychological factors influencing the neurophysiologic regulation of sleep.

apprehensive worry that makes sleep even less likely, causing a vicious circle. These challenges of dysfunctional thinking about sleep may be targeted through education and cognitive treatment.

Maladaptive Sleep Practices. Going to bed less than an hour later after getting back to home from an evening work shift or exercising late at night (with the hope of exhausting oneself) are perfect examples of maladaptive sleep practices that are indeed counterefficient. Playing video games or engaging telephonic conversation or intellectual process also fall in this category (see Table 6.5 for an exhaustive list).

Emotional Arousal. The autonomic and hormonal systems react easily to stress and emotion and have the potential to disrupt normal sleep mechanisms (Vgontzas et al., 1998). Personality traits can determine people more

at-risk of developing chronic insomnia, such as people with strong self-inhibition, perfectionism, excessive worrying, or depression.

Behavioral Interventions. Behavioral therapy is a psychotherapy based upon the principles of classical conditioning focusing on physical and psychological aspects to optimize sleep onset, maintenance, promote activities that are conducive to sleep, and regularize sleep-wake schedules. It can be used appropriately both for the treatment of psychophysiological insomnia (primary insomnia) and comorbid insomnia consecutive of a medical or psychiatric disorder. There are usually several different approaches, which may be combined, as briefly described below:

- (1) Relaxation techniques: targets the somatic and psychic-cognitive stress factors perpetuating insomnia.

6.5

Examples of Maladaptive Sleep Practices That May Favor Insomnia

Sleep-related habits and daily life practices that may interfere with sleep

Practices that reduce homeostatic drive at bedtime

Daily life behaviors

- Insufficient activities during the day
- Lying down to get rest during the day

Sleep-related habits

- Napping, nodding, and dozing off during the day or evening
- In a trance, semiawake in the evening
- Spending too much time in bed
- Extra sleep on weekends

Practices that disrupt circadian regularity

Daily life behaviors

- Insufficient morning light exposure, leading to a phase delay in circadian rhythm
- Early morning light exposure, producing early morning awakening owing to a phase advance in circadian rhythm

Sleep-related habits

- Irregular sleep-wake schedule
- Sleeping-in in the morning during weekends

Practices that enhance the level of arousal

Daily life behaviors

- Excess caffeine consumption or caffeine later in the day
- Smoking in the evening
- Alcohol consumption in the evening
- Exercising in the late evening
- Late evening meal (may cause nocturnal acid reflux) or fluid (may cause frequent urination)
- Getting home late or insufficient time to wind down

(continued)

6.5

Examples of Maladaptive Sleep Practices That May Favor Insomnia (*continued*)

Sleep-related habits

- Evening apprehension of sleep
- Preparations for bed are arousing
- No regular presleep ritual
- Distressing pillow talk
- Watching television, reading, engaging in other sleep-incompatible behaviors in bed before lights out, or falling asleep with television or radio left on
- Trying too hard to sleep
- Clock watching during the night
- Staying in bed during awakenings or lingering in bed awake in the morning
- Nonconducive sleep environment, such as bed-partner snoring, noises, direct morning sunlight, or pets in the bedroom

It has reported to shorten sleep onset latency, decrease wake time after sleep onset, increase total sleep time, and improve sleep quality.

- (2) Stimulus control: strengthen the association of the bedroom and sleep.
- (3) Temporal control: promotes regularity of bedtime and awakenings while eliminating daytime naps.
- (4) Sleep restriction: involves increasing homeostatic sleep drive by reducing time in bed with the hope to improve sleep efficiency. Naps are proscribed.

Behavioral therapy seems to have credits in the treatment of insomnia as a majority of patients (from 50% up to 80%) report net benefit from it. Behavioral therapy using a combination of techniques has been reported to be effective compared to placebo in a double-blind study for the short-term treatment of insomnia, with an outcome similar to classical pharmacological treatments, showing a significant improvement in sleep onset latency, wake time after sleep onset, and total sleep time (Edinger, Wohlgemuth, Radtke, Marsh, & Quillian, 2001; Morin, et al., 2004; Morin et al., 1994; see Figure 6.20).

While it might take time before seeing significant benefits, behavioral therapy can also be pursued safely for a very long time, unlike most of the associated pharmacological treatments. This constitutes a major advantage for the treatment of chronic, long-lasting insomnia.

Regarding nonpharmacological treatments, physical exercise shows merit and should be recommended by health care professionals (Montgomery & Dennis, 2002). Good sleep hygiene including a regular sleep-wake cycle with regular exercise in the morning or afternoon should be preferred. However, intensive physical activity soon prior to bedtime is known to interfere with sleep (Becker, 2006b; Kupfer & Reynolds, 1997; Ohayon & Roth, 2003). Bright light exposure should happen throughout the course of the day, while dim lighting prior to bed should be favored (Montgomery & Dennis, 2002). Meals rich in lipid content, as well as stimulants, alcohol, and nicotine should be avoided at all cost at least 3 hours prior to bedtime (2001).

So far, however, cognitive-behavior therapy, involving stimulus control, sleep restriction, sleep hygiene,

6.1

Quick Points About Insomnia

Figure 6.20 Efficacy of cognitive-behavioral therapy on the treatment of chronic insomnia.

and relaxation, seems to be the current front runner in terms of efficiency for nonpharmacological treatments (Baillargeon, et al., 2003).

Due to the likelihood of multifactorial causes, the best approach in our opinion remains a care management approach using several modes of care, through a controlled combination of pharmacological intervention coupled to nonpharmacological approaches (cognitive, physical therapies, and education). A physician specialist in sleep medicine should critically guide this approach upon accurate diagnosis of the sleep disorder and identification of plausible underlying causes, preferentially. Any other approach would still remain a prime example of *iatrogenesis imperfecta* (see Exhibits 6.1 and 6.2).

Hypersomnia: Focus on Narcolepsy-Cataplexy

Falling asleep at inappropriate times such as behind the wheel, or manipulating a dangerous object or machine, may have dramatic consequences. At least, when simply occurring during a conversation or a regular day-life activity, they might have detrimental outcomes on social and professional interactions, since it can impair driving ability, cause car or machine accidents, reduce professional performance leading to people becoming

PREVALENCE AND ASSOCIATED COST

- About 30 % of adults have symptoms of insomnia; 10 % of them have chronic insomnia
- Increased mortality
- Economic loss

IDENTIFIABLE SYMPTOMS OF INSOMNIA DISORDER

- (1) Trouble falling asleep or difficulty staying asleep
- (2) Waking up too early or not feeling refreshed after sleep
- (3) These symptoms occur despite opportunity of regular sleep time
- (4) At least one of the following problems is reported:
 - Low daytime energy
 - Daytime sleepiness
 - Lack of motivation
 - Attention, concentration, or memory problems
 - Poor performance at school or work
 - Extreme mood changes
 - Errors at work or while driving
 - Tension, headaches, or stomachaches
 - Frustration or worry about sleep
- (5) Those with the following conditions are at risk:
 - Sleep disorder
 - Medical condition
 - Mental health disorder
 - Substance abuse

unemployed, changing jobs frequently, or retiring early (Beusterien, 1999; Broughton, et al., 1981; Findley, 1995; Kales, et al., 1982). Falling asleep during these circumstances are all abnormal situations testifying to hypersomnia.

Hypersomnia, most characterized by excessive daytime sleepiness, is the very opposite of insomnia. Related to the difficulty in staying awake, hypersomnia may be caused by a wide spectrum of syndromes such as among the most prevalent, obstructive sleep apnea/hypopnea syndrome, narcolepsy-cataplexy, idiopathic hypersomnia, and recurrent hypersomnia.

Excessive daytime sleepiness is a symptom that occurs in about 5 % of the adult population in Westernized

6.2

Quick Facts About Treatment

- Self-treatment rarely works, might be under-efficient, or poorly targeted.
- Over-the-counter medications are not proved to be effective, may constitute a health danger (hepatotoxicity), and should be avoided.
- Combination of behavioral therapy with FDA-approved medicine is the most effective form of treatment.
- Ramelteon (Rozerem) and zolpidem are the most effective pharmacological choices.
- Ramelteon has fewer reported side effects and constitutes probably the most natural way of inducing sleep.
- Ramelteon and zolpidem are prescription medications and should not be confused with over-the-counter medications.

countries. Chronic (excessive) daytime sleepiness affects largely prefrontal cortex and results directly in a fall of alertness, deterioration of concentration and attention, deterioration of short-term memory, recollection of events, and mood swings. Language and creativity can also deteriorate while distraction by irrelevant information develops or increases. Hallucinations and altered perception of reality might also appear. Physical performance is also very easily impaired by chronic daytime sleepiness, and severe excessive daytime sleepiness can lead to dysarthria, tremor, ptosis, nystagmus, and epileptic seizures.

Among the syndrome causing excessive daytime sleepiness is narcolepsy-cataplexy. It is a neurological sleep disorder characterized by a tetrad of symptoms: (1) persistent and disabling daytime sleepiness, and manifestations of REM sleep physiology during wakefulness, that is, (2) cataplexy, (3) sleep paralysis, and (4) hypnagogic hallucinations (Bassetti & Aldrich, 1996). Cataplexy is a partial or total sudden loss of muscle tone, similar to that normally observed during REM sleep but occurring as a result of an emotional stimulus. Sleep paralysis, related to REM sleep atonia, is the inability to control when falling asleep or on waking any striated muscles controlling voluntary movement. Hypnagogic hallucinations are vivid dream-like experiences occurring the transitional state between wakefulness and sleep.

Epidemiology

Narcolepsy-cataplexy has a prevalence of about 1 per 2,000 humans of the general population in the United States (Dement, 1973). It is estimated that this condition afflicts about 200,000 Americans, with less than 50,000 actually diagnosed. Japan has the highest prevalence of narcolepsy with about 1 per 600 individuals, and Israel the lowest, with 1 per 50,000 individuals (Lee-Chiong & Teofilo, 2008).

Age of onset spans from adolescence to adulthood, with a first peak around 15 years of age and a second one around 35 years of age, with slight differences across populations (Dauvilliers et al., 2001; Figure 6.21).

Some major events such as trauma, pregnancy, or major psychological stress, are reported by more than 50% of the patients prior to the onset of symptoms. Excessive daytime sleepiness is generally the first symptom to appear. It can be followed or not by cataplexy, sleep paralysis, and hypnagogic hallucinations. Several years separate the emergence of initial symptoms and the diagnosis and care of narcolepsy.

Clinical Manifestation of Narcolepsy

The tetrad of symptoms (excessive daytime sleepiness, cataplexy, sleep paralysis, and sleep hallucinations) as-

Figure 6.21 Age onset distribution in narcoleptic populations.

From "Narcolepsy with Cataplexy," by Y. Dauvilliers, I. Arnulf, & E. Mignot, 2007, *Lancet*, 369(9560), p. 500. Copyright ©2007 by Elsevier. Reprinted with permission.

sociated with narcolepsy are heavily disabling consequences due to significant and chronic disorganization of sleep-wake behavior. The systematic presence of all the symptoms is, however, reported only in 10%–15% of patients.

Chronic excessive daytime sleepiness is present in all the patients with narcolepsy, and is an indicator of the disorder. It is typically the first, primary, and most disabling of manifestation of the disorder but intensity varies across the day and between individuals (Scammell, 2003). Sleepiness is enhanced by periods of inactivity and improved temporarily after short naps. Naps lasting from 10 to 20 minutes can occur up to 8 times during the day. Sleepiness can lead to unconscious microsleep episodes, lapses, or sleep attacks.

REM sleep manifestations during wakefulness is also part of the tetrad of symptoms that a narcoleptic patient can develop: cataplexy is observed in about 70%–80% of patients, hypnagogic hallucinations for 8%–70%, and sleep paralysis in 5%–65% of patients. These symptoms can be combined and occur systematically with EDS.

Cataplexy is defined by a sudden, transient, and bilateral loss or reduction of postural muscle tone occurring during wakefulness. It is triggered by emotional factors, such as laughter, pleasant surprise, excitement, embarrassment, or anger (Dauvilliers, Arnulf, & Mignot, 2007). All striated muscles but the diaphragm can be affected resulting in collapse without consciousness impairment, while most attacks are usually partial affecting only facial muscles or limbs. Cataplexy occurs only with narcolepsy and is the best diagnostic marker of the disease. Cataplexy attacks are usually short in duration (from less than a second to several minutes) with a very variable frequency (less than one episode per year to several episodes per day). Cataplectic rebound (called status cataplecticus) is frequently observed upon abrupt withdrawal from antidepressant drugs used for cataplexy (Poryazova, Siccoli, Werth, & Bassetti, 2005). As discussed later, this rebound is not observed with other non-antidepressant drugs.

Sleep paralysis involves a transient loss of the ability to move that occurs at the onset of sleep (hypnagogic) or on awakening (hypnopompic). It occurs in about 5%–65% of persons with narcolepsy. All striated muscles are affected except respiratory and ocular muscles. It is usually as short as a few seconds but can last up to several minutes in rare instances, and can end either spontaneously or following sensorial stimulation.

Hypnagogic hallucinations are seen in about 8%–70% of patients having narcolepsy (Dauvilliers et al., 2001), but are not pathognomonic for narcolepsy

(Ohayon, 2000). These hallucinations are vivid dream-like hallucinations made of auditory, visual, somesthetic, or kinetic content. They are sometimes frightening. By definition hypnagogic hallucinations occur during the transition from wakefulness to sleep, while some cases of hypnopompic hallucinations, occurring on awakening) have also been reported.

Narcoleptic patients tend to have a greater tendency for having higher body-mass indices than those without the disease (Okun, Lin, Pelin, Hong, & Mignot, 2002), which may result from a lower metabolic rate, due to hypocretin deficiency, affecting feeding and metabolism. Patients with narcolepsy may have a greater risk of developing depression (up to 37% of patients; Roth & Nevsimalová, 1975; Vandeputte & de Weerd, 2003) and type 2 diabetes mellitus (Lee-Chiong & Teofilo, 2008).

Despite the fact of an irresistible drive for sleep during the day, nocturnal sleep is also disturbed. Although narcoleptic patients fall asleep very quickly and have a total regular sleep time, their sleep is of poor quality due to frequent arousals and awakenings.

Neurophysiology of Narcolepsy

Though discovered more than 100 years ago by Westphal (1877) and Gélinau (1881), the underlying cause of narcolepsy remained elusive until very recently. In 1930, helped by postmortem analysis lesions, von Economo predicted an involvement the posterior hypothalamus. In 1999, two consecutive publications reported a mutation in the hypocretin (orexin) receptor 2 gene, linking directly narcolepsy with a deficient hypocretin transmission due to a loss of hypocretin neurons (Chemelli et al., 1999; Lin et al., 1999). So far, narcolepsy is the sleep-disorder having received the greatest attention from researchers, in particular at the molecular level.

Genetic factors play an important role since first-degree relatives have a 40-fold increased risk of developing narcolepsy (Guilleminault, Mignot, & Grumet, 1989; Mignot, 1998) but individual's genetic background is not sufficient to explain hypocretin deficiency fully (Mignot, 1998). The presence of human leukocyte antigens is a strong genetic factor but can only support, not determine diagnosis. These findings support a multifactorial model for the development of narcolepsy, with a strong influence from environmental factors, acting in combination with genetic factors, possibly triggering an autoimmune process with irreversible damages to the orexin/hypocretin system. The link with the immune processes may be through a genetic tendency to release a particular pattern of inflammatory mediators, such as cytokines, which lead to the sleep abnormalities (Shneerson, 2000).

There is usually no obvious trigger for narcolepsy but environmental events during early development could influence the likelihood of developing the disease, or its severity. Though the nature of the environmental trigger remains unknown, it is frequently associated with stressful events (Orellana, et al., 1994).

In 1999, a group lead by Emmanuel Mignot at Stanford discovered that a mutation in the hypocretin-2 receptor gene was the cause of familial canine narcolepsy (Lin, et al., 1999). Hypocretin receptor-2 gene knockout mice have also been engineering showing evidence of similar narcoleptic phenotype to that seen in human narcolepsy with fragmented sleep-wake patterns, cataplexy, and premature entrance into REM sleep (Willie, et al., 2003).

The neural correlates in humans seem to be similar. Sleepiness may be related to the loss of hypocretin neurons that stimulate arousal processes involving the LDT-PPT cholinergic nuclei and tuberomammillary histaminergic nuclei. Cataplexy might result from the same physiological processes leading to REM sleep atonia, though it is debated. Cataplexy is produced by inhibition of lower motor neurons by cholinergic areas of the pons and basal forebrain. It is believed that cataplexy results from a loss of hypocretin-induced excitation of the locus coeruleus (NA) and dorsal raphe (5-HT) that inhibit cholinergic neurons located in the LDT-PPT. The de-inhibited LDT-PPT, when stimulated by the limbic system (in response to an emotion), stimulates the nucleus gigantocellularis, leading to a glycine-mediated hyperpolarization of the anterior horn of the spinal cord (Lee-Chiong, 2008). Mignot and colleagues reported that about 90% of patients with narcolepsy-cataplexy have no detectable hypocretin-A in their cerebrospinal fluid, which constitutes a useful diagnosis criterion assessed via lumbar puncture.

To fully understand why a loss of hypocretin signaling can cause narcolepsy, we need to come back to the fundamentals of sleep/wake control. Because of its associated symptoms, narcolepsy is regarded as a tendency to a mixed sleep-wake state in which REM sleep intrudes into non-REM and wakefulness. From the first part about non-pathological sleep, we remember that the presences of aminergic neurons (NA, 5-HT, HIS) in the rostral brain stem and in the TMN, dopaminergic neurons (in the ventral periaqueductal gray), are wake promoting. REM sleep is produced through the interaction of aminergic and cholinergic neurons of the LDT-PPT, during which NA and 5-HT become inactive. The ventrolateral preoptic area (VLPO) is essential to produce non-REM sleep (its lesion produce marked insomnia) and inhibits wake-promoting regions (TMN, LC, DR). In turn VLPO is inhibited by these amines.

Thus, this sleep/wake control is markedly controlled by a reciprocally inhibitory circuit in which wake- and sleep-promoting regions inhibit one another, creating a “flip-flop switch” (Saper, et al., 2001). A critical element of this switch for a correct regulation of sleep/wake pattern is to have a bistability property. This is exactly what is lacking in narcolepsy with an irresistible sleep, intrusions of REM-like phenomena, and nocturnal awakenings, which all result from abnormally low thresholds to transition between wakefulness, REM, and NREM sleep (Scammell, 2003). In non-pathological sleep, a prolonged period of wakefulness—despite a gradually increasing sleep pressure—is achieved through an additional stabilizing influence provided by the neuropeptide hypocretin/orexin. Hypocretin neurons found in the posterior and lateral hypothalamus have excitatory influence onto aminergic that promote wakefulness and inhibits REM sleep (Chemelli, et al., 1999; Peyron, et al., 1998). Suppression of REM sleep by hypocretin may occur via activation of aminergic areas (NA, 5-HT, HIS), which inhibits the REM-producing cholinergic neurons located in the LDT-PPT. Figure 6.22 summarizes the underlying neurophysiology.

Hypocretin neurons are also involved in the regulation of feeding, sympathetic tone, and motor activity (Date, et al., 1999; Hara, et al., 2001), and may also have a significant role in circadian rhythm. Narcoleptic patients have a mild overweight (10%–15%) compared to normal subjects, even though when their diet is similar (Lammers, et al., 1996; Schuld, et al., 2000), most likely due to a decrease in their metabolic rate for which hypocretin neurons have also an influence.

The process that causes this loss of hypocretin is still unknown but it is proposed that this selective loss of hypocretin neurons could be the result of an autoimmune or neurodegenerative process though compelling evidence is still lacking. Recent data report, however, an increased gliosis in the hypocretin neurons region which can be consistent with a neurodegenerative or inflammatory process (Peyron, et al., 2000; Thannickal, et al., 2000).

Pharmacological Treatment of Narcolepsy

Narcolepsy is a chronic disease. Once established, the symptoms of narcolepsy remain more or less stable, although cataplexy may sometimes improve in time. Since there is no cure for narcolepsy at this time, the aim of all therapeutic approaches is to control the symptoms in a lifelong treatment (Bhat & El Solh, 2008). In order to manage successfully a pharmacological treatment of

France in 1994 and in 1998 by the FDA. The molecular structure of modafinil is different from amphetamines, which suggests a different mechanism of action. While modafinil has demonstrated as efficient as classical central nervous system stimulants, it has a major advantage due to its safer pharmacological profile with a lower frequency and severity of side effects. It has also a much lower abuse potential. Since it is a long-acting stimulant, it is better tolerated than short acting drugs, such as methylphenidate.

The mechanism of action of modafinil is still unclear. It is believed to affect both adrenalin, noradrenalin, serotonin, histamine, dopamine, and GABA systems (Lin, et al., 1992; Mignot & Nishino, 2005; Saper & Scammell, 2004). Modafinil enhances the activity of the hippocampus (Kim, et al., 2007) and wake-promoting sites, including the hypocretin region (Scammell, et al., 2000). Dopamine reuptake inhibition seems to be involved as well. Modafinil can disinhibit some regions involved in the control of wakefulness via a reduction of extracellular GABA concentrations through serotonergic mechanisms (Ferraro et al., 1996a). Modafinil increases hepatic cytochrome P450 enzymes, and therefore increase the metabolism of other drugs and decrease their associated peak plasma concentration, including oral contraceptives.

Unlike amphetamine-like drugs, strong efficacy of modafinil on EDS has been demonstrated by randomized, double-blind, placebo-controlled trials (Beustermen, et al., 1999; Billiard, et al., 1994; Broughton, 1997; Moldofsky, et al., 2000). Its wide efficacy combined with fewer sympathomimetic effects and little or no evidence of tolerance contributed to the fact that modafinil is currently the most widely prescribed drug for EDS. Importantly, withdrawal of modafinil does not result in a rebound of REM and SWS, unlike sympathomimetics.

Studies reported that modafinil is safe, well tolerated, and effective for the long-term treatment of EDS associated with narcolepsy and significantly improves perceptions of general health (Becker et al., 2004; Fry & U.S. Modafinil in Narcolepsy Multicenter Study Group, 2000; Mitler, Harsch, Hirshkowitz, & Guilleminault, 2000; Moldofsky, et al., 2000). It has also been demonstrated that modafinil is best supplemented by sodium oxydate for optimum results in treating narcolepsy due to positive additive effects (Amulf & Mignot, 2004).

An enantiomeric form of modafinil, called armodafinil, has been approved in 2007. Because of its longer half-life than modafinil, armodafinil has a more prolonged effect during the day and potential improve-

ment in sleepiness in the late afternoon and early evening (Bhat & El Solh, 2008).

Other Stimulants. Selegiline, pemoline, and mazindol have also been used in the treatment of excessive daytime sleepiness with more or less efficiency. Selegiline is an irreversible monoamine oxidase type-B inhibitor mainly used in Europe. It produces dose-dependent REM suppression during sleep and increase REM latency (Reinish, MacFarlane, Sandor, & Shapiro, 1995). Cases of severe toxicity have been reported.

Pemoline is an oxazolidine derivative, which selectively blocks dopamine re-uptake and mildly enhances dopamine release. Sleepiness is moderately improved with pemoline and reports of fatal hepatotoxicity forced its withdrawal.

Mazindol is an imidazolidine derivative, which blocks noradrenalin and dopamine re-uptake. It has been withdrawn because of valvular abnormalities.

Treatment of Cataplexy

Because of their anticataplectic effects at low doses besides their antidepressant properties, tricyclic antidepressants have been considered for decades as a treatment of choice for cataplexy, and are indeed the most effective treatment of REM-dissociation symptoms. Selective serotonin and norepinephrine reuptake inhibitors antidepressants have progressively replaced tricyclics, due to their low adverse effects. Antidepressants are, however, not currently approved by the FDA to treat this specific symptom and rebound cataplexy is commonly observed upon abrupt withdrawal of antidepressants (Dauvilliers et al., 2007; Poryazova et al., 2005).

Tricyclic Antidepressants. This category usually includes clomipramine, desipramine, imipramine, and protriptyline, which have been extensively used for cataplexy. Adverse effects due to their anticholinergic properties, such as dry mouth, increased sweating, weight gain, orthostatic hypotension, anorexia, diarrhea, tiredness, and decrease libido have also been reported (Doghramji, et al., 2007). These side effects triggered the development of alternative treatments, including selective reuptake inhibitors.

Selective Serotonin Reuptake Inhibitors (SSRIs). Fluoxetine (Prozac) and fluvoxamine (Luvox) are members of the most recent generation of SSRIs. Because of their minimal anticholinergic and antihistaminic adverse effects compared to tricyclic antidepressants, fluoxetine

and fluvoxamine are commonly used in psychiatry (Fluoxetine mostly for depression and fluvoxamine for obsessive-compulsive disorder). Higher doses are required to observe anticataleptic properties.

Venlafaxine is a selective serotonin-norepinephrine reuptake inhibitor (Horst & Preskorn, 1998) with pharmacological properties (lower stimulant effect and shorter half-life) that are preferred over those of fluoxetine for the treatment of cataplexy.

Though tricyclic drugs are usually more effective than SSRIs and SNRIs, their side effects put them as a side choice, especially because they can exacerbate EDS.

It is interesting to note that the anticataleptic effect of antidepressants is apparent within one day, whereas relief of depression often takes around two weeks, suggesting a mechanism of action most likely different from antidepressant action (Shneerson, 2000).

Sodium Oxybate. Gammahydroxybutyrate (GHB, sodium oxybate, Xyrex) was first proposed as treatment of REM-dissociation symptoms by Broughton and Mamelak in 1979. GHB is not an antidepressant but a sedating drug and is the only medication approved by the FDA for the treatment of cataplexy. GHB may also improve the (subjective) quality of nocturnal sleep, which is usually disturbed in narcoleptic patients. Double-blind placebo-controlled studies demonstrated a significant reduction in cataplectic attacks in patients affected by narcolepsy-cataplexy, who were administered sodium oxybate nightly (U.S. Xyrem Multicenter Study Group, 2004). Because of its very short half-life, two doses taken at night are required.

Unlike other drugs used for cataplexy, sodium oxybate has the advantage to show an absence of tolerance, an absence of cataplexy rebound upon abrupt withdrawal, and a higher efficiency. Common adverse effects are reported such as nausea, headache, dizziness, and enuresis, and because of its abuse potential, sedating and hypnotic properties (used as a so-called rape drug), distribution and use of sodium oxybate is severely monitored. In a paper published in 2004, the group of Emmanuel Mignot at Stanford investigated the efficiency of classical pharmacological treatments for narcolepsy on 270 adult patients affected by this disorder. They concluded that modafinil and sodium oxybate produced additive effects when used together, and were currently the most efficient in treating EDS in patients with narcolepsy and cataplexy (Arnulf & Mignot, 2004).

Current available medications do not allow patients with narcolepsy to maintain normal and consolidated

state of alertness, therefore management of narcolepsy should be supplemented with nonpharmacological approaches and behavioral strategies.

BEHAVIORAL APPROACHES

Sleep hygiene must be optimized with the maintenance of a regular sleep-wake schedule as much as possible. Major shifts in circadian rhythms such as jet lag or shift work should be avoided. Short naps during the day may also help relieve temporarily patients with sleepiness. Because the beneficial effect of naps in narcoleptic patients is only transient, several short naps (max. 30 minutes) should be scheduled across the day to optimize patient's refreshment, especially prior to demanding activities (Nishino, 2007). However, a prolonged inactivity during the daytime might exacerbate some narcoleptic symptoms.

Practicing a physical activity might also improve sleep quality as long as it does not occur within 3 hours prior to bedtime. It may also help control gain weight, which is a common side effect of narcolepsy, and relieve from stress. Finally, some narcoleptic patients may be more sensitive than normal subjects to the sleep-inducing properties of carbohydrates, and therefore they should restrain to consume large carbohydrate-rich meals.

Evidence-Based Clinical Management of Behavioral Nutrition

Janet Colson

Walter de la Mare was accurate in his nursery rhyme “That whatever Miss T. eats, Turns into Miss T.” The foods that we consume have a tremendous impact on what we become and how our bodies function. Over the last 4 decades, there has been an increasing interest on the impact that foods have on a variety of health issues, with recent interest focusing on diet and behavior.

Nutrient intake can influence the brain, and subsequently behavior, in two main ways. First, specific nutrients in the diet can influence the brain’s structure and function. For example, the brain is a very fatty organ. About 60% of the brain’s dry weight and 80% of nerve cells are fat. Long-chain polyunsaturated fatty acids (LCPUFA) make up 20%–25% of the fat content (Benton, 2008b; Hadder-Algra, 2008). The impact that the types of dietary fat (i.e., saturated or unsaturated fats) have on brain and behavior is an area of growing interest.

The second way diet affects behavior is linked to how nutrients are delivered to cells and the efficiency with which nutrients are metabolized. Foods vary in their digestibility, absorbability, and transport, which affect the rate at which that nutrients are delivered to cells. This, in turn, have a short-term influence on behavior.

This chapter outlines current research on the impact of dietary intake on behavior. Since fatty acid in-

take is the aspect of nutrition that has been studied the most, the main focus will be fats, mainly the impact of omega-3 (n-3) fatty acids on human behavior.

THE FATTY ACIDS

Omega-6 Versus Omega-3

The majority of lipids in foods and the body are made of long-chain fatty acids (LCFAs). Fluidity of fatty acids is influenced by the number of double bonds in the chain. Saturated fatty acids have no double bonds, which makes them solid, since the hydrocarbon chains that form them are very tightly packed, preventing fluidity. Examples of saturated fatty acids include the fat on bacon and prime rib, coconut oil, and butter. In contrast, fluidity of the unsaturated fatty acids increases as the number of double bonds increases. Because of their ability to flow, LCFAs are very often referred to as oils. The two main classes of LCPUFA are the omega-3 (n-3) and the omega-6 (n-6) fatty acids.

Fatty acids have common names but also are identified by a shorthand system indicating the number of carbon atoms, the number of double bonds, and the site of the first double bond from the terminal methyl group or the omega (n) end. For example, linoleic acid (LA) is

the trivial name for the fatty acid that is made of 18 carbons and has two double bonds, with the first double bond on the sixth carbon (n-6) from the omega end. The shorthand notation is 18:2n-6. LA was first identified as an essential fatty acid in 1929, when husband-and-wife team George and Mildred Burr conducted studies that confirmed it was a dietary essential for rats. Growth failure, dermatitis, loss of water through the skin, and fatty liver were among the symptoms caused by LA deficiency (Burr & Burr, 1929). During the 1960s, the consumption of high-LA vegetable and seed oils, such as corn, sunflower, and safflower oils, was recommended. Reports at that time showed a decrease in serum cholesterol and, presumably, a reduction in cardiovascular disease, with high polyunsaturated fatty acid (PUFA) intake (Grundy et al., 1982). Figure 7.1 illustrates how LA may be elongated and desaturated to form the 20-carbon arachidonic acid (ARA; 20:4 n-6) and elongated again to form the 22-carbon adrenic acid (ADA; 22:4n-6).

There are three main long-chain n-3 fatty acids of dietary significance. First is the 18-carbon alpha lino-

lenic acid (ALA; 18:3n-3), which is found in some plant foods such as flax seed, soybean, canola, wheat germ, and walnuts oils. The other two are the highly unsaturated eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3). EPA and DHA are commonly called fish oils since they are abundant in cold-water fishes. ALA was recognized as an essential fatty acid in the 1950s, while initial interest in EPA and DHA surfaced in the 1970s when it was discovered that Greenland Eskimos, whose diets are high in n-3 fats, had very low mortality from cardiovascular disease (Dyerberg, Bang, & Hjerne, 1975; Leaf, 2008). The main role of ALA was assumed to be as a precursor to the longer-chained, more highly saturated EPA and DHA, since, theoretically, ALA can be elongated and desaturated to the longer, more highly unsaturated LCFA. However, Sontrop and Campbell (2006) report that humans have a limited capacity to elongate and desaturate ALA to EPA and DHA, with less than 1% converted in humans. Most of the ALA is oxidized to energy. Additionally, the same enzymes are used to synthesize the n-6 fatty acid ARA from LA, as is required to elongate ALA

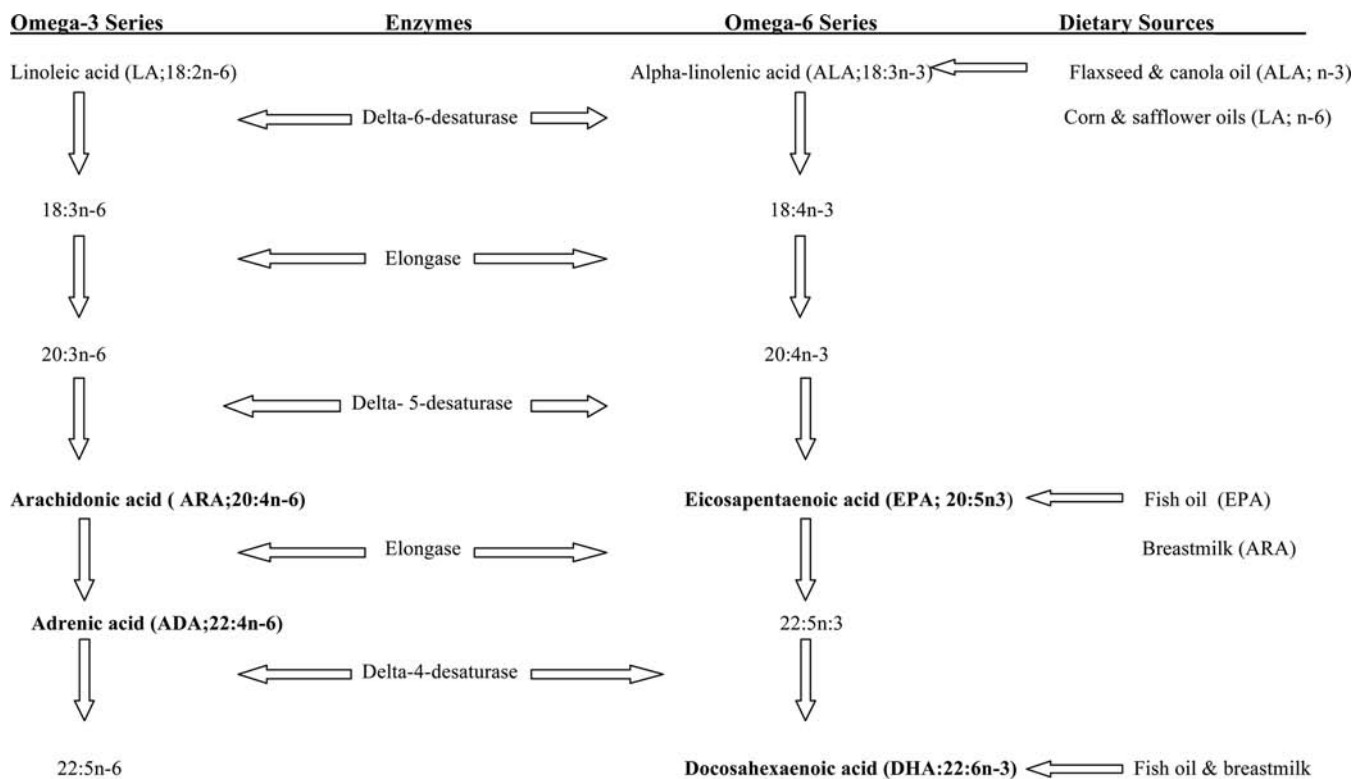

Figure 7.1 Metabolic pathways for polyunsaturated fatty acids.

Adapted from Parker et al., 2006.

to EPA and, subsequently, to DHA. Hence, competition exists when excessive amounts of either ALA or LA are consumed.

Typical Dietary Intake and Sources of n-3 Fatty Acids

Direct intake of EPA and DHA from fish oil, either in the supplemental form or from oily fishes, is important since the enzyme pathway required to synthesize them from ALA is relatively inefficient. Americans, on average, consume about 1,300 mg of ALA per day but only 100 mg of EPA and DHA combined (Arterburn, Hall, & Oken, 2006). People who consume cold-water fishes and other seafood have higher intakes, since they are the best sources of EPA and DHA, as shown in Table 7.1.

All common cooking oils used in Western societies contain predominately n-6 fatty acids. Even the “heart healthy” Canola oil is 18% n-6 (as LA) with 9% n-3 (as ALA). Corn oil is 53% n-6 (as LA), with less than 1% n-3 (as ALA). When the ratios of n-6 to n-3 are considered, corn oil has about a 50:1 ratio, while canola’s ratio is closer to 2:1 (U.S. Department of Agriculture, 2008). Because of heavy reliance on cooking oils, the ratio of n-6 to n-3 is much higher now than it was in the past. Rees, Austin and Parker (2005) point out: “Man has evolved on a diet with an omega-6 to 3 ratio of 1:1 whereas today this ratio is greater than 10:1” (p. 275). This change in ratio has been linked to a myriad of health problems common in modern Western civilizations, including cardiovascular disease, certain cancers, impaired immune functioning, and recently reported behavioral problems.

With the growing interest in n-3 fatty acids, supplementation in many processed foods is increasing. Manufacturers of processed foods such as margarine, bread, mayonnaise, pizza, yogurt, orange juice, pasta, and infant formula are increasing production of n-3 fortified products, with most from ALA.

Dietary Recommendations Related to Omega-3 Fatty Acids

The Food and Nutrition Board of the Institute of Medicine of the National Academies of Science (2005) establishes the acceptable intake (AI) and acceptable macronutrient distribution range (AMDR) for lipids. The AI for total n-3 is 1,600 mg per day for men and 1,100 mg per day for women, while the AMDR is 0.6%–1.2% of total energy. Approximately 10% of the AMDR should be consumed as EPA and/or DHA. This amount is low compared to

the American Heart Association’s recommendations of 500 to 1,800 mg of EPA and DHA to reduce “cardiac and all-cause mortality” (Kris-Etherton, Harris, & Appel, 2002, p. 2754).

Two servings of fatty fish each week will provide the desirable amount of EPA and DHA and is the recommended dietary approach. One capsule of most standard supplements will provide 180 mg of EPA and 120 mg of DHA. Therefore, three capsules are required to receive approximately 900 mg. The American Heart Association recommends that “fried fish (e.g., from restaurants and fast-food establishments, as well as many frozen, convenience-type fried fish products) should be avoided because they are low in omega-3 and high in *trans*-fatty acids” (Kris-Etherton et al., 2002, p. 2752).

The U.S. Dietary Recommendations, found in Table 7.2, is a set of general nutrition-related lifestyle recommendations for healthy people in the America (U.S. Department of Health and Human Services & U.S. Department of Agriculture, 2005). Two of the nine recommendations deal with fat intake. The main recommendations related to fats are to:

- (1) Limit fat intake to between 20% and 35% of calories daily. This translates to 44 to 78 grams of fat for a person who consumes 2,000 calories per day.
- (2) Limit intake of saturated and trans fats found in margarine, shortening, and many baked goods while selecting foods rich in unsaturated fats, such as vegetable oils, fatty fish, and most nuts.

Omega-3 Fatty Acids in the Body

Fatty acids, including ALA, EPA, and DHA, are embedded in phospholipids that form the lipid bilayers of cell membranes. One of the primary modes of action for the 20-carbon ALA and EPA is the formation of 20-carbon eicosanoids. Examples of eicosanoids include the prostaglandins, thromboxanes, and leukotrienes that function as autocrines, hormones that act on the same cells that secrete them. Eicosanoids are produced when a hormone (e.g., insulin) or a cytokine (e.g., interleukin) binds to the plasma membrane receptor. The n-3-derived eicosanoids exert beneficial antithrombotic and anti-inflammatory actions, while those formed from the n-6 ALA tend to have antagonistic effects (Spector, 2006). EPA is now confirmed to be an effective cardiovascular protectant by the American Heart Association (Kris-Etherton et al., 2002).

DHA forms the 22-carbon docosanoid family of autocrines, which are abundant in retinal and brain

Omega-3 Fatty Acid Content as EPA, DPA, and DHA in Selected Fish and Seafood

FOOD (100 g OR ~3.5 OZ SERVING)	EPA (20:5 n-3)	DPA (22:5 n-3)	DHA (22:6 n-3)
Herring			
Atlantic	909	71	1,105
Pacific	1,242	220	883
Anchovies , canned in oil	763	41	1,292
Halibut			
Greenland	674	114	504
Atlantic/Pacific	91	121	374
Mackerel	504	106	699
Tuna			
Blue fin	363	160	1,141
Canned in water, light	47	9	223
Canned in water, white	233	18	629
Sardines	473		509
Salmon			
Atlantic—farm raised	690	NA	1,457
Atlantic—wild	411	463	1,429
Canned, pink drained	359	108	693
Rainbow trout			
Farmed	36	334	840
Wild	120	468	520
Flounder (3 oz)	207	207	219
Catfish, farmed	49		128
Oysters	260		291

7.2

U.S. Dietary Guidelines: Summary of Key Recommendations for the General Population

ADEQUATE NUTRIENTS WITHIN CALORIE NEEDS
<ul style="list-style-type: none"> ■ Consume a variety of nutrient-dense foods and beverages while limiting intake of saturated and trans fats, cholesterol, added sugars, salt, and alcohol.
WEIGHT MANAGEMENT
<ul style="list-style-type: none"> ■ Balance calories from foods and beverages with calories expended. ■ To prevent gradual weight gain over time, make small decreases in food and beverage calories and increase physical activity.
PHYSICAL ACTIVITY
<ul style="list-style-type: none"> ■ Engage in regular physical activity and reduce sedentary activities to promote health, psychological well-being, and a healthy body weight. ■ Achieve physical fitness by including cardiovascular conditioning, stretching exercises for flexibility, and resistance exercises or calisthenics for muscle strength and endurance.
FOOD GROUPS TO ENCOURAGE
<ul style="list-style-type: none"> ■ Choose a variety of fruits and vegetables each day. Select from all 5 vegetable subgroups (dark green, orange, legumes, starchy vegetables, and other vegetables). ■ At least half the grains should come from whole grains. ■ Consume 3 cups per day of fat-free or low-fat milk or equivalent milk products.
FATS
<ul style="list-style-type: none"> ■ Consume less than 10% of calories from saturated fatty acids and less than 300 mg per day of cholesterol, and keep trans fatty acid consumption as low as possible.

(continued)

7.2

U.S. Dietary Guidelines: Summary of Key Recommendations for the General Population (*continued*)

- Keep total fat intake between 20% and 35% of calories, with most fats coming from sources of polyunsaturated and monounsaturated fatty acids, such as fish, nuts, and vegetable oils.
- Limit intake of fats and oils high in saturated and/or trans fatty acids, and choose products low in such fats and oils.

CARBOHYDRATES

- Choose fiber-rich fruits, vegetables, and whole grains often.
- Choose and prepare foods and beverages with little added sugars or caloric sweeteners.

SODIUM AND POTASSIUM

- Consume less than 2,300 mg (approximately 1 teaspoon of salt) of sodium per day and increase potassium rich foods.

ALCOHOLIC BEVERAGES

- Those who choose to drink alcoholic beverages should do so sensibly and in moderation—defined as the consumption of up to one drink per day for women and up to two drinks per day for men.

FOOD SAFETY

- To avoid microbial food borne illness:
 - Clean hands, food contact surfaces, and fruits and vegetables. Meat and poultry should not be washed or rinsed.
 - Separate raw, cooked, and ready-to-eat foods while shopping, preparing, or storing foods.

Note: The Dietary Guidelines for Americans 2005 contains additional recommendations for specific populations. The full document is available at www.healthierus.gov/dietaryguidelines.

phospholipids. Docosanoids are anti-inflammatory and protect against brain injury due to ischemia-reperfusion (Spector, 2006). In addition, the highly unsaturated nature of DHA enables it to be flexible and transition rapidly between large numbers of conformations, providing an optimum environment for the function of membrane-bound proteins. This unique property is thought to be necessary for the optimum function of membranes that must rapidly expand to excitation, such as neural synapses. Because of these differences, DHA is more involved in structure-enhancing fluidity, while EPA is more involved in function through the many roles of eicosanoids.

The National Institutes of Health hosts the EFA Education Site (<http://efaeducation.nih.gov>), which was developed by the Polyunsaturated Fatty Acid Special Interest Group. The site provides extensive infor-

mation, slide presentations, and video links on EPA and DHA.

The Brain: A Fatty Organ

The brain grows most rapidly during the last trimester of the fetal period until age 2 years and continues to grow until late adolescence (Hadders-Algra, 2008). By 2 years of age, the brain is about 80% of the adult weight and by 6 years the brain is about 95% of its final size. The gray matter continues thickening and peaks around puberty. The gray matter of the frontal area is particularly involved in judgment, organization, and planning. Gray matter thins as unused connections are pruned and the cells die (Benton, 2008b).

Nutrient deficiency during the rapid growth period in the first years of life may have adverse effects on later

cognitive functioning and behavior (McCann & Ames, 2005). AHA and DHA are particularly important at this time. Adequate ARA status is crucial during the early stage of gestation, while DHA is more critical during later pregnancy. DHA in the brain increases approximately 30-fold from the last trimester to 2 years of age (Mitmesser & Jensen, 2007). Data from metabolic and postmortem studies show that the fetus accumulates an average of 67 mg of DHA per day (Innis, 2003). Infants born prematurely are at special risk for n-3 insufficiency because they may not have benefited from a full trimester of receiving the mother's lipid stores. Preterm infants have very limited ability to synthesize DHA from the shorter-chain ALA; therefore DHA supplementation is crucial for normal growth and development. After birth, n-3 status depends on the infant's innate lipid metabolism and dietary intake of DHA and ALA from breast milk and/or formula (Kidd, 2007).

DHA is required for the development of the sensory, perceptual, cognitive, and motor neural systems during the brain growth spurt. EPA's importance to the brain's development is unclear. Since colostrum and breast milk contain a much smaller amount of EPA than DHA, it is assumed that EPA is not as crucial as DHA (Brenna, Varamini, Jensen, Diersen-Schade, Boettcher, & Arterburn, 2007). Laboratory animals (rodents and primates) with experimentally induced n-3 deficiencies show deficits in cognitive performance, retinal structure, and visual acuity development. The importance of DHA to brain development is related to the neurons that continually form axons and dendritic extensions with accompanying cell membranes. Growing membranes must be relatively fluid, and DHA is the most fluidizing substance in cell membranes. The synapses, the primary functional units of brain circuits, are made from membranes preferentially enriched in DHA (Kidd, 2007). Membrane fluidity also affects membrane-bound enzymes, receptors, and channel ions (Rees, Austin, & Parker, 2005).

McCann and Ames (2005) published an extensive review on the importance of DHA during development of cognition and normal brain function. Within the limits imposed by performance testing of infants and toddlers, they concluded that:

- In animals whose brain concentrations of DHA were severely reduced, dietary supplementation with DHA restored control performance levels.
- Studies with human infants suggest supplementation with DHA in formula or by boosting maternal levels enhances neuromotor development.
- Application of a wide range of tests yielded a positive association between breast-feeding and infant men-

tal performance. (Breast milk is an excellent natural source of DHA.)

Although it is difficult to test cognitive performance within the first year, infants who were fed breast milk or formulas with DHA were found (within a few months after birth) to have superior visual acuity compared to those fed less than adequate DHA. The superior visual function persists through the first year after birth and perhaps into the seventh year or later (McCann & Ames, 2005).

METHODS AND INSTRUMENTS TO USE WHEN ASSESSING NUTRITIONAL STATUS

Since nutritional status may affect psychological well-being, nutrition indicators should be considered in a complete assessment of patients. This section provides a brief overview of nutritional assessment techniques. For a more comprehensive reference, refer to *Nutritional Assessment* by Robert Lee and David Nieman (2006). The four ways to assess nutritional status are anthropometric measurements, biochemical tests, clinical observations, and dietary intake evaluation.

Anthropometry is the measurement of various dimensions of the body. Typical measurements include weight and height/length and, for infants and toddlers, head circumference. Estimates of the percent of fat and muscle in the body may also be determined. Anthropometrics are useful to psychologists for determining desirable weight status and degrees of under- or overweight. Tracking weight at weekly intervals is useful when one is working with patients exhibiting disordered eating patterns or those on weight loss programs.

Biochemical tests are typically done on blood samples and are used to validate intake of certain nutrients. The majority of tests use blood samples that are analyzed for nutrient levels or enzyme activity that reflects nutrient utilization or stores. Examples include blood glucose levels, hematocrit, hemoglobin, creatinine, and serum levels of most minerals and many vitamins. Other nutrient-related biochemical tests include analysis of hair or nails to determine levels of trace minerals such as lead or mercury.

Clinical observations involve careful observation of physical signs of nutritional status, such as skin color, swollen glands, fatigue, appearance of skin, and edema. This can also involve checking for vital signs

such as the pulse rate, respiration, temperature, and blood pressure.

Dietary evaluations provide information about the food intake of an individual or a group of people. The type of evaluation used depends on the desired outcome and the availability of staff and funding. Also, some dietary evaluation strategies require a considerable amount of time for the patient to complete, which decreases accuracy and their usefulness. A psychologist may find that contracting with an outside agency is more cost effective than having nutritional assessments completed in-house, especially if a study is being conducted with a large sample. Two centers that offer consulting on a contractual basis are the Arizona Diet, Behavioral, and Quality of Life Assessment Center and the Fred Hutchinson Cancer Research Center. Both provide consultation on the most appropriate type of nutrition assessment to use, design the instruments, and collect and analyze the nutritional data. The four main types of nutrition evaluations are found in Table 7.3, with strengths and weaknesses highlighted for each.

IMPACT OF OMEGA-3 FATTY ACIDS ON COGNITION

Fatty Acid Needs During Gestation

For years fish has been considered “brain food” because of its fatty acid content. Recent studies have examined the impact that consumption of fish and n-3 fatty acids has on cognition at various stages of the life cycle.

Since brain development begins during the embryonic period of pregnancy, both maternal ARA and DHA status must be adequate to ensure adequate supply to the fetus. Hadders-Algra (2008) published a review of studies that dealt with prenatal PUFA status. Based on results of the 12 observational studies reviewed, she concludes that prenatal ARA status shows a positive relationship to neurodevelopmental outcome in infancy, but not at older ages, while prenatal DHA status results in improved test scores and other cognitive measures in the offspring at older ages, but not during infancy. Of the eight intervention studies reviewed, she found three that had very promising results to support beneficial effects of LCPUFA. Studies by Helland and associates found similar results, suggesting that prenatal DHA supplementation has little benefit in terms of cognitive functioning for infants (up to 12 months), but found positive effects on cognitive outcome at the ages of 4 and 7 years (Helland, Saugstad, Smith, Saa-

rem, Ganes, & Drevon, 2001; Helland, Smith, Blomén, Saarem, Saugstad, & Drevon, 2008; Helland, Smith, Saarem, Saugstad, & Drevon, 2003).

Hadders-Algra (2008) also points out that “the recommendation of a current consensus meeting, which suggested that dietary fat intake during pregnancy and lactation should be as recommended for the general population and include at least 200 mg DHA per day. Even higher dosages may be beneficial, in particular when applied during the last trimester of gestation and lactation” (p 102). She concludes that ARA and DHA supplementation may be associated with subtle benefits in terms of development outcome.

Interestingly, the “heart-unhealthy” trans-fatty acids, found mainly in margarines, baked goods, and convenience foods, may have a negative impact on brain function. Bouwstra et al. (2006) examined fatty acid content in the umbilical cord and found that trans-fatty acid status has a substantial negative effect on neurologic condition at 18 months of age. It is possible that the hard consistency of trans-fatty acids has a negative impact on fluidity of membranes. These findings give new meaning to the recommendation of the U.S. Dietary Guidelines to reduce trans-fatty acid intake as much as possible. In addition to the cardiovascular benefits, there may be additional brain-enhancing benefits when intake of trans fats is reduced.

One problem with DHA supplements is they may have a negative impact on ARA. ARA is crucial for early brain development, since it is elongated to ADA, which is needed for myelin formation. High DHA levels compete with enzymes, resulting in decreases in ARA and ADA. Care must be taken to ensure an adequate ARA-to-DHA ratio.

Maternal Fish Intake and Child Development Outcome

Several studies have reported evidence of a link between maternal fish consumption during pregnancy and positive child development outcome (Oken et al., 2005, 2008a, 2008b). However, contaminants in fish such as mercury raise concerns about fish consumption during pregnancy (Myers & Davidson, 2000; Myers et al., 2003). Oken et al. (2005) followed 135 mother-infant pairs to investigate whether maternal fish consumption during pregnancy harms or benefits fetal brain development. Cognition was assessed by the percent novelty preference on visual recognition memory (VRM) testing at 6 months of age. Mothers consumed an average of 1.2 fish servings per week during the sec-

7.3

Types of Dietary Evaluations with Strengths and Weaknesses

TYPE	DESCRIPTION	STRENGTHS	LIMITATIONS
24-Hour Recall	The 24-hour recall is an in-depth interview that collects detailed information on all foods and beverages consumed by a participant during the previous 24 hours. It may be done in person or over the phone or Internet. A computerized nutrient database is used to analyze foods for nutrient content.	<ul style="list-style-type: none"> (1) Requires less than 20 minutes to complete (2) Inexpensive (3) Only requires short-term memory (4) Can provide detailed information on food 	<ul style="list-style-type: none"> (1) Seldom representative of usual intake (2) Under- or over-reporting may occur (3) Omissions of dressings, sauces and beverages may lead to underestimation of calories (4) Requires memory
Food Record or Diary	A food record or food diary is a detailed description of all foods and beverages consumed over a period of 3–7 days. Foods are recorded by the patient at the time of consumption. A computerized nutrient database is used to analyze foods.	<ul style="list-style-type: none"> (1) Does not depend on memory (2) Can provide detailed intake data (3) Multiple day data more representative of usual intake 	<ul style="list-style-type: none"> (1) Requires high degree of cooperation (2) Subject must be literate (3) Act of recording may alter diet
Food Frequency Questionnaires	The food frequency questionnaire is the most commonly used dietary assessment tool in large epidemiologic studies of diet and health. Typically a booklet asks participants to report the frequency of consumption and portion size of meals over a defined period of time (e.g., the last month, the last three months).	<ul style="list-style-type: none"> (1) Self-administered (2) Machine readable (3) Relatively inexpensive (4) May be used for large-scale studies (5) Method of choice for diet-disease relationships 	<ul style="list-style-type: none"> (1) May not represent usual foods or portion sizes chosen by respondent (2) Intake data can be inaccurate when multiple foods are in one category (3) Depends on ability of subject to describe the diet
Food Accounts	A food account measures dietary intake in households and institutions. It accounts for all food on hand in the home or institution at the beginning of the survey plus all that is brought in and again at the end of the study period. Food consumed is calculated from the difference and divided by the number of people eating in the home or institution.	<ul style="list-style-type: none"> (1) Good for use with large sample sizes (2) Can be used over relatively long periods (3) Gives data on family or group eating habits (4) Less likely to lead to alterations in the diet (5) Relatively economical 	<ul style="list-style-type: none"> (1) Does not account for food losses (2) Respondent literacy and cooperation needed (3) Does not measure individual food consumption

ond trimester. Higher fish intake was associated with higher infant cognition. For each additional weekly fish serving, offspring VRM score was 4.0 points higher. However, an increase of 1 ppm in mercury was associated with a decrement in VRM score of 7.5 points. VRM scores were highest among infants of women who consumed more than 2 weekly fish servings but had mercury levels less than 1.2 ppm.

Oken and colleagues (2008a) followed a similar protocol, using a larger sample of 341 mother-child pairs, and followed them for 3 years. Cognition in children was assessed by the Peabody Picture Vocabulary Test and Wide Range Assessment of Visual Motor Abilities at age 3 years. Mean maternal total fish intake was 1.5 servings per week, and 40 mothers (12%) consumed more servings per week. Mean maternal mercury level was 3.8 ng/g. Higher fish intake was associated with better child cognitive test performance, and higher mercury levels with poorer test scores. Fish consumption of 2 or fewer servings per week was not associated with any benefit. In both studies, Oken and colleagues concluded that women should continue to eat fish during pregnancy but choose varieties with lower mercury levels.

Low-mercury fish and shellfish include shrimp, clams, salmon, tilapia, pollack, sole, flounder, catfish, whiting, oysters, sardines, haddock, anchovies, herring, and scallops. Salmon, oysters, sardines, anchovies, and herring are also excellent sources of n-3 fatty acids. Groth (2008) has pointed out that “no variety of canned tuna is on the list” (p. 236). Although canned tuna was the most frequently consumed fish product among the subjects in the study reported by Oken et al. (2003), it does not meet the criteria for low-mercury fish. One serving (170 g) of canned “light” tuna provides, on average, about 20 ug of mercury, while a similar amount (170 g) of canned white (albacore) tuna contains 60 ug of mercury.

More recently, Oken et al. (2008b) examined 25,446 Danish children and found that higher maternal fish intake and greater duration of breast-feeding are associated with higher child intelligence at 18 months. So, encouraging patients to increase intake of low-mercury fish is a logical recommendation. Since fish is the main source of EPA and DHA, it is assumed that this is the content of fish that makes fish “brain food.”

Impact of Breast-Feeding on Cognition

Many reports support the finding that children and adults who were breast-fed for longer periods had higher scores on tests of cognitive function, with benefits among pre-

term infants more pronounced than among full-term infants (Anderson, Johnstone, & Remley, 1999; Jain, Concato, & Leventhal, 2002; Kaneko et al., 2001; Mitmesser & Jensen, 2007; Mortenson, Michaelsen, Sanders, & Reinisch, 2002). Interpretation of such findings has been based almost entirely on observational studies that fail to control adequately for confounding factors, such as maternal intelligence and quality of parenting (Anderson et al., 1999; Jacobson & Jacobson, 2002; Jain et al., 2002). The results of the Promotion of Breastfeeding Intervention Trial, the largest randomized trial ever conducted in the area of human lactation, showing that prolonged and exclusive breast-feeding improves children’s cognitive development, based on Wechsler Abbreviated Scales of Intelligence (WAIS) measures and teachers’ academic ratings of both reading and writing (Kramer et al., 2008). The study sample included 17,046 healthy breast-feeding infants, of whom 13,889 (81.5%) were followed up at age 6.5 years.

The impact that breast-feeding has on adult intelligence was reported by Mortenson et al. (2002), who followed over 3,000 individuals from age 18 to 27 years. They found the “positive effects of breast-feeding continue into young adulthood. Duration of breastfeeding was associated with significantly higher scores on the Verbal, Performance, and Full Scale WAIS IQs. With regression adjustment for potential confounding factors, the mean WAIS IQs were 99.4, 101.7, 102.3, 106.0, and 104.0 for breastfeeding durations of less than 1 month, 2 to 3 months, 4 to 6 months, 7 to 9 months, and more than 9 months, respectively” (p. 2365).

A number of studies have suggested that breast-fed infants perform better than formula-fed infants. Breast milk is rich in DHA and ARA, typically reflecting maternal dietary intake. Standard infant formulas are poor sources, especially of DHA. Formula companies such as Mead Johnson Nutritionals introduced infant formulas with added DHA and ARA in 2002 in the United States (Mitmesser & Jensen, 2007). For formula-fed infants, studies have reported mixed results from DHA or DHA plus ARA supplementation (Wright, Coverston, Tiedeman, & Abegglen, 2006). There are several important differences among LCPUFA studies with term infants that may contribute to the differing results, including levels of LCPUFA added to the formula, variations in test methods, ages of infants evaluated, and sources of LCPUFA. Nevertheless, several expert groups recommend that infant formulas be supplemented with DHA and ARA. Recommendations for term infants for DHA and ARA range from 0.2% to 0.4% and from 0.35% to 0.7% of the fatty acids, respectively (Mitmesser & Jensen, 2007).

Exercise, DHA, and Memory

Physical activity may improve memory (Churchill et al., 2002; Whitbourne, Neupert, & Lachman, 2008). In a meta-analysis of studies on humans over age 55 years, Angevaren, Aufdemkampe, Verhaar, Aleman, and Vanhees (2008) reported that 8 out of 11 studies showed that aerobic exercise coincided with improvements in cognitive capacity in adults over age 55 years. The largest effects on cognitive function were found on motor function and auditory attention. Moderate effects were observed for cognitive speed and visual attention.

It appears that the type of dietary fat consumed may also influence memory. Animal studies suggest that diets high in saturated fat and refined sugar (like typical Western diets) can interfere with neuronal plasticity and compromise capacity of the brain for learning while reducing the levels of the brain-derived neurotrophic factor (BDNF) that enhances synaptic plasticity and is a predictor of learning efficacy (Greenwood & Winocur, 1996; Molteni, Barnard, Yin, Roberts, & Gómez-Pinilla, 2002; Winocur & Greenwood, 1999). Molteni, Wu, Vaynman, Ying, Barnard, and Gómez-Pinilla (2004) expanded the studies by examining the effect that exercise has on BDNF and the memory of rats that were given a high-fat and high-sugar diet for 2 months. Results showed that exercise prevented the deficit in spatial learning induced by the diet. The authors suggest that exercise interacts with the same molecular systems disrupted by the high-fat diet, reversing their effects on neural function.

Wu, Ying, and Gómez-Pinilla (2008) suggest that DHA enhances the effects that exercise has on memory. They found that a short 12-day exposure to a DHA-enriched diet significantly increases learning ability and the effects are enhanced by the concurrent application of voluntary exercise. The effects of the DHA diet and exercise on cognitive enhancement were paralleled by elevations in BDNF, and the activated forms of the synaptic protein CREB (cAMP response element binding). The enhanced actions of the DHA diet and exercise on cognition and neuroplasticity suggest a possible mechanism by which specific aspects of lifestyle integrate their actions at the molecular level to influence neuronal function. Wu and colleagues speculate on the existence of four possible mechanisms:

- (1) DHA is converted to neuroprotectin D1, which can elevate levels of BDNF.
- (2) DHA acts on plasma membranes that may activate signaling mechanisms that can result in more BDNF.

- (3) The antioxidant capacity of DHA may help reduce oxidative stress that has been shown to decrease BDNF.
- (4) DHA may help transport glucose across the brain-blood barrier to provide an energy source for the neurons.

Glucose Metabolism, Omega-3, and Memory

The impact that DHA has on glucose metabolism has been described by Pifferi and colleagues (2007). They examined the impact of n-3 PUFA on expression of the glucose transporter GLUT1 in endothelial cells of the blood-brain barrier in rats. Results show a decrease of GLUT1 by 23% in the n-3 deficient, and an increase of 35% in those fed a high-n-3 diet. The authors suggest that n-3 PUFA intake could be a useful dietary approach to correct impairments of cerebral glucose metabolism, especially during aging. Increases in glucose uptake by the brain will improve cognitive ability.

The Role of n-3 Fatty Acids in Dementia and Alzheimer's Disease in the Elderly

With the rapid growth in the elderly population and accompanying cognitive decline and dementia associated with aging, more emphasis is being placed on studies that focus on this population and associated problems. Some very interesting and somewhat conflicting results have been reported on the role of n-3 fatty acids on cognition in elders.

Virtanen, Siscovick, Longstreth, Kuller, and Mozafarian (2008) followed 3,660 older adults and found that those who ate broiled or baked tuna and other fish high in n-3 fatty acids 3 times or more per week had a nearly 26% lower risk of having silent brain infarcts that can cause dementia and stroke than those who did not regularly eat fish. Food frequency questionnaires were used to determine fish consumption patterns. After adjustment for multiple risk factors, the incidence of infarct was found to be lower among those consuming tuna or other fish 3 times per week than among those who consumed fish less than once per month. One serving per week reduced risk by 13%. Eating fried fish was not protective. Fish consumption was also related to fewer changes in white matter of the brain.

When cognitive performance is measured, the impact of n-3 intake is not as clear cut. In a double-blind, placebo-controlled study of 302 healthy older adults by

van de Rest et al. (2008), EPA-DHA supplements had no impact on cognitive performance. Participants were randomly assigned to one of three groups: the first received 1,800 mg EPA-DHA per day, the second received 400 mg EPA-DHA per day, and the third received placebo capsules. Cognitive performance was assessed by an extensive neuropsychological test battery that tested the cognitive domains of attention, sensorimotor speed, memory, and executive function. After 26 weeks, there were no significant changes in any of the cognitive domains for either low-dose or high-dose fish oil supplementation compared with the placebo.

It is possible that supplements are not as protective as whole foods. There may be other substances in fish that are the brain-enhancing chemicals. Also, long-term consumption may have a more positive impact than the relatively short 26-week study. Another possibility is the impact of n-3 fatty acids on memory is complicated by the type of apoproteins to which people are genetically predisposed.

Apolipoproteins, n-3 Fatty Acids, and Alzheimer's Disease

Recent evidence points to the role that apolipoproteins play in memory and dementia. Apolipoproteins (Apo) are proteins found in the external phospholipid layer of lipoproteins. They are important in maintaining the structural integrity and solubility of lipoproteins, play an important role in lipoprotein receptor recognition, and regulate certain enzymes in lipoprotein metabolism. There are several alphabetical classes of apolipoproteins, including ApoA, ApoB, ApoC, ApoD, and ApoE. ApoE was initially recognized for its importance in lipoprotein metabolism and cardiovascular disease. More recently, it has been studied for its role in several biological processes not directly related to lipoprotein transport, including Alzheimer's disease and cognition. The gene encoding for ApoE has three alleles— $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$; of these, only $\epsilon 4$ is associated with greater risk of cognitive decline (Hill, Bhattacharjee, & Neumann, 2007; Y. Huang, Weisgraber, Mucke, & Mahley, 2004; Whalley, Deary, Starr, Wahle, Rance, & Bourne, 2008).

Whalley et al. (2008) investigated the impact of n-3 PUFA to cognitive aging in the presence and absence of the *ApoE* 4 allele. They measured the cognitive decline in 120 volunteers born in 1936, at the approximate ages of 64, 66, and 68 years. Total n-3 PUFA and DHA concentrations were associated with benefits for cognition at age 64 years and from ages 64 to 68. They found a positive association between n-3 PUA and sustained

cognition, but only in the absence of the *ApoE* 4 allele. This is an area of growing interest, and the presence of the *ApoE* 4 allele should be considered when one is working with the elderly, especially dementia patients.

Studies of omega-3 fatty acids and dementia have had mixed results. A report by Schaefer et al. (2006) using subjects from the Framingham Heart Study analyzed the relationship between dementia and DHA levels. They drew the blood of 899 men and women with an average age of 76 years and looked at the association between dementia and DHA levels. Participants also completed a self-administered food frequency questionnaire that assessed their diet, including fish consumption. After 9 years, participants were split into quartiles based on the levels of DHA in their blood. The quartile with the highest DHA levels had a 47% lower risk of developing dementia and 39% lower risk of developing Alzheimer's disease than the remaining three quartiles. The participants in the top quartile reported in their food frequency questionnaires that they ate an average of 180 mg of DHA daily, and an average of 2.9 servings of fish a week. Ninety-nine new cases of dementia (including 71 of Alzheimer's disease) occurred during the follow-up. A 50% reduction in the risk of Alzheimer's disease was associated with the consumption of more than 2 servings of fish per week. The authors concluded: "In the future, it will also be important to determine whether combined dietary supplementation with DHA can decrease further mental deterioration in patients with established dementia" (Schaefer et al., 2006, p. 1549).

The probable mechanism of DHA on brain functioning involves the role of DHA in the membrane of ion channels in the brain, which allows them to change shape more easily and transmit electrical signals. This mechanism could explain the role of DHA not only in dementia and cognition, but in most aspects of behavior.

MOOD AND RELATED DISORDERS

Depression

Over the last 2 decades, there has been an increased interest in the link between diet and depression, particularly in the n-3 fatty acids. A review by Parker, Neville, Brotchie, Heruc, Rees, and Hadzi-Pavlovic (2006) concluded, "Deficits in omega-3 fatty acids have been identified as a contributing factor to mood disorders and offer a potential rational treatment approach" (p. 996). Both biochemical and epidemiological studies provide evidence of the link. More recently, several intervention

studies have examined the therapeutic role of n-3 fatty acids in depressive disorders.

Lipid status may be assessed either by measurement of blood lipid levels, an indication of short-term intake, or by measurement of adipose tissue levels, an indicator of long-term or habitual intake. In the early 1980s, Lieb, Karmali, and Horrobin (1983) reported high blood levels of AA-derived eicosanoids in patients with depression. Sontrop and Campbell (2006) reviewed more recent studies (from 1996 to 2003) on the blood lipid levels of depressed patients. They found 6 case control studies that showed low ratios of n-3 to n-6 in depressed patients compared to non-depressed controls. Sontrop and Campbell pointed out potential PUFA-related confounders in case control studies and concluded that most of the six studies:

- Excluded subjects with obvious physical impairments that could interfere with PUFA status;
- Controlled for smoking status, since it affects PUFA metabolism;
- Included only subjects who had not used antidepressants or antipsychotics for at least eight days; and
- Assumed subjects consumed an adequate amount of energy, since a low intake could also decrease PUFA intake.

The second method of biochemical analysis involves measuring composition of adipose tissue, using a gas chromatograph. Mamalakis spearheaded several studies in Crete examining relationships between lipid status and depression (Mamalakis, Jansen, Cremers, Kiriakakis, Tsibinos, & Kafatos, 2006; Mamalakis, Kalogeropoulou, et al., 2006; Mamalakis, Kiriakakis, Tsibinos, & Kafatos, 2004; Mamalakis, Tornaritis, & Kafatos, 2002). They found that mildly depressed lawyers had lower levels of DHA than non-depressed subjects (Mamalakis et al., 2002) and replicated the study with a different adult population and found the same low DHA levels linked to increased depression (Mamalakis, Kalogeropoulou, et al., 2006). They were the first to report a relationship between adipose tissue ALA and depression in the elderly (Mamalakis et al., 2004). They also found that elderly depressed males had lower adipose ALA and total n-3 fatty acids than non-depressed ones (Mamalakis, Jansen, et al., 2006). This study also examined serum cholesterol and found no significant differences between depressed and non-depressed serum cholesterol levels.

Epidemiological studies in the 1990s examined possible links between fish consumption and mood disorders (Weissman et al., 1996). Increases in seafood

consumption are linked to a lower incidence of depressive disorders. In population studies in Iceland and Japan, those with high fish consumption, and therefore EPA and DHA, had lower depressive problems (Cott & Hibbeln, 2001; Magnusson, Axelsson, Karlsson, & Oskarsson, 2000). In addition, as the eating habits of people from the Arctic region become more Westernized, rates of depression increase (McGrath-Hanna, Greene, Tavermier, & Bult-Ito, 2003).

Parker et al. (2006) summarized studies linking seafood consumption with decreased incidence of depression (Table 7.4). Of the six studies they examined, only one, by Hakkarainen, Partonen, Haukka, Virtamo, Albanes, and Lonnqvist (2004), reported no association between n-3 or fish intake and mood. Interestingly, it is the only one of the six that used a validated food frequency questionnaire. The others used population consumption rates or brief questionnaires. In the Hakkarainen study, self-reported depressed mood was recorded 3 times annually, and major depressions documented by hospital admission and suicides were identified from death certificates. No significant association found between dietary intake and any outcome variable. However, dietary intake, rather than the actual biochemical levels, was determined. Another consideration of the study was that dietary n-3 intake included the 18 carbon ALA, which has a poor conversion to EPA or DHA. Therefore, the actual EPA and DHA consumption could have been very low.

It is interesting to consider the triangle effect that may exist between cardiovascular disease (CVD), depression, and n-3 fatty acids. Typically, patients with CVD are at increased risk for depression and have lower n-3 fatty acid status. A question to consider is, if n-3 status is improved, would there be an improvement in CVD risk, with concurrent decrease in depression score?

Postpartum Depression

Postpartum depression (PPD) rate is approximately 10%–15% worldwide, although rates of mild postpartum mood changes as high as 80% have been reported (Llorente, Jensen, Voigt, Fraley, Berretta, & Heird, 2003). PPD is defined as a “spectrum of affective illness follows childbirth, from the common, mild, and transient baby blues to postpartum (puerperal) psychosis, which can be classed among the most severe episodes of illness seen in clinical practice (Forty et al., 2006, p 1549). Typically the onset is within 4 weeks after delivery. Evidence supports the hypothesis that low DHA levels increase PPD. Hibbeln (2002) reported that both lower seafood consumption and DHA content of mother’s milk are very

Adapted from "Omega-3 Fatty Acids and Mood Disorders," by G. Parker, A. G. Neville, H. Brotchie, G. Heruc, A. M. Rees, & D. Hadzi-Pavlovic, 2006, *American Journal of Psychiatry*, 163.

strongly correlated ($r = 0.81$) with increased prevalence of the disorder. He found that EPA and ARA levels were unrelated to the PPD rate. From a biochemical standpoint, maternal blood levels of DHA become depleted during the last trimester, since fetal accretion averages 67 mg per day (Innis, 2003), and may take up to one year to normalize (Sontrop & Campbell, 2006). DHA levels decrease further in lactating women as a result of the DHA being incorporated into mother's milk.

Results of two cohort studies provide strong evidence of a link between DHA and PPD. Otto, de Groot, and Hornestra (2003) used the Edinburgh Postnatal Depression Scale to retrospectively measure depression levels 32 weeks after delivery. PPD was associated with slower normalization of DHA to desirable levels. There was no association between PPD and any other PUFA level. Concentrations of EPA, DHA, and total n-3 PUFA were lower, with concentrations of LA, ARA, and total n-6 higher among the depressed women than among the non-depressed women. De Vries, Christophe, and Maes (2003) found similar results in their study, which examined blood lipid levels taken shortly after delivery, with no additional follow-up blood work. PPD scores were measured between 24 and 40 weeks postpartum. Their results found a higher ratio of n-6 to n-3 in women with PPD than in those without.

Freeman, Hibbeln, Wisner, Brumbach, Watchman, and Gelenberg (2006) assessed the efficacy of n-3 fatty acids for PPD in an 8-week dose-ranging trial. Subjects were randomized to 0.5 g per day ($n = 6$), 1.4 g per day ($n = 3$), or 2.8 g per day ($n = 7$). At baseline, the mean Edinburgh Postnatal Depression Scale (EPDS) and Hamilton Rating Scale for Depression (HRSD) scores for all three groups were 18.1 and 19.1, respectively. Post-treatment mean scores were 9.3 and 10.0, resulting in percent decreases on the EPDS and HRSD of 51.5% and 48.8%, respectively. Changes from baseline were significant within each group and when groups were combined. The treatment was well tolerated. Limitations of their study included the small sample size and lack of a placebo group. However, these results were promising and encourage further study of n-3 fatty acids as a treatment for PPD.

In a follow-up study, Freeman, Davis, Sinha, Wisner, Hibbeln, and Gelenberg (2008) investigated use of n-3 fatty acids for PPD combined with supportive psychotherapy. They used a slightly larger sample of 51 women randomized into either an n-3 group taking 1,900 mg per day (as DHA + EPA) or a placebo group. Again, subjects were followed for 8 weeks. They did not find a benefit in supplements versus placebo, since participants in both groups experienced significant decreases

in Edinburgh Postnatal Depression Scale and Hamilton Rating Scale for Depression scores ($p < 0.0001$) from baseline. There was no significant difference between n-3 fatty acids and placebo in this study, in which all participants received supportive psychotherapy, which may have limited the ability to detect an effect of n-3. The authors concluded that the manualized supportive psychotherapy warrants further study. They also pointed out that "low intake of dietary omega-3 fatty acids among participants is of concern, in consideration of the widely established health advantages in utero and in infants" (Freeman et al., 2008, p. 142).

Other Mood Disorders

In addition to depression and PPD, n-3 fatty acid status has been linked to other behavioral problems such as schizophrenia, suicide, and bipolar disorder.

- **Schizophrenia**—In a 6-month study involving people with schizophrenia who were treated with EPA or a placebo, the placebo group clearly lost cerebral tissue, while the patients given the supplements had a significant increase of gray and white matter (Puri, 2006).
- **Bipolar disorder**—Stoll et al. (1999) conducted a double-blind, placebo-controlled study of patients diagnosed with bipolar disorder. Half of the 30 patients received capsules containing olive oil, and the other half received capsules containing 9 g of n-3 as EPA and DHA. Subjects in the n-3 group were less likely to experience a relapse of symptoms in the 4 months of the study. Moreover, the n-3 group experienced significantly more recovery than the placebo group.
- **Suicide**—Several studies have examined levels of n-3 fatty acids and suicide. Epidemiologic studies show that low fish intake is a risk factor of suicide (Partonen, Haukka, Virtamo, Taylor, & Lonnqvist, 1999). In a case and control study, Huan et al. (2004) reported that EPA levels in red blood cells in the case subjects were significantly lower than those of the control subjects. They concluded that "low n-3 fatty acid levels in tissues were a risk factor of suicide attempt and suggested that further studies including intervention with fish oil are needed" (Huan et al., 2004, p. 490). Sublette, Hibbeln, Galfalvy, Oquendo, and Mann (2006) followed 33 medication-free depressed subjects for two years. Seven subjects attempted suicide on follow-up. Low plasma DHA and a higher ratio of n-6 to n-3 predicted suicide attempts. The authors speculate that the finding could have "implications for the neurobiology of suicide and reduction of suicide risk" (Sublette et al., 2006, p. 1100).

- *Self-reported mental well-being*—Mental and physical well-being were compared to EPA and DHA levels in serum phospholipids in 2,416 people over age 15. Results suggest a strong and consistent association between EPA and self-reported physical well-being; the association with mental well-being was less compelling (Crow, Skeaff, Green, & Gray, 2007).
- *Attention-deficit/hyperactivity disorder*—Children with ADHD have lower levels of ARA, EPA, and DHA than those without attention problems (Burgess, Stevens, Zhang, & Peck, 2000). Vaisman et al. (2008) reported that attention improved in children ages 8–13 who were diagnosed with ADHD when their diets were supplemented with n-3 fatty acid.

Proposed Mechanisms Linking n-3 and Depression

The n-3/depression mechanism appears to be linked to increases in prostaglandins derived from ARA, which lead to decreased BDNF levels and/or alterations in blood flow to the brain

Low brain n-3 fatty acids are thought to lower the transmission of dopamine, possibly contributing to the negative and neurocognitive symptoms in schizophrenia and other disorders. This is called the *n*-3 polyunsaturated fatty acid/dopamine hypothesis of schizophrenia (Ohara, 2007).

A second mechanism is called the macrophage theory of depression. Increased levels of macrophages, white blood cells that aid in immunity, are associated with depression. Sontrop and Campbell (2006) explain that clinical depression is “accompanied by an over activity of the inflammatory response of the immune system . . . and the increased secretions of cytokines and eicosanoids” (p. 11). Administration of inflammatory cytokines to humans causes a range of psychiatric symptoms similar to those found in depression. High dietary intake of n-6 fatty acids results in formation of the proinflammatory eicosanoids, while the n-3 from fish oils decreases them.

The other mechanism is the cAMP signal transduction hypothesis, which suggests that depression and bipolar disorders may be caused by impaired phospholipid metabolism and impaired fatty acid-related signaling (Sontrop & Campbell, 2006).

Concerns About n-3 PUFA Supplements

One concern many nutrition experts have regarding recommendations for n-3 supplements is their potential

side effects. Comparing the possible adverse effects to concerns about the safety of standard antidepressants, psychologists Rees et al. (2005) acknowledge that “There is a relative lack of knowledge about the safety of standard antidepressants in the perinatal period. There is a clear need for more research into alternative treatments, such as omega-3 fatty acids, in the management of depression in the perinatal period” (p. 274).

RESEARCH RELATED TO OTHER NUTRIENTS AND BEHAVIOR

In addition to consumption of adequate essential fatty acids, general dietary status affects brain functioning and behavior. Benton (2008a) described the influence of diet on children’s cognition and behavior (Table 7.5). The brain requires high amounts of glucose for normal functioning. The frequency, amount, and type of foods consumed affect glucose availability to the brain. With changes in family dynamics, (e.g., increases in single parent households and working mothers), the meal patterns and food selections of today’s children and adults are changing. More children either skip breakfast or have sugar-coated cereals with a sugary beverage, and more adults opt for cappuccino or soda with a rich pastry.

The changing dietary trends have increased the amount of foods that have a high glycemic index (GI). GI is a measure of the rise in blood glucose after consumption of a particular carbohydrate-containing food. Carbohydrates that break down rapidly during digestion, causing glucose to flood the bloodstream, have a high GI; carbohydrates that break down slowly, releasing glucose gradually into the bloodstream, have a low GI. Numerous health problems, including type 2 diabetes, hypercholesterolemia, and behavioral problems, are associated with foods that have a high GI.

Vitamins and minerals are considered micronutrients because they are needed in milligram or microgram amounts, while we typically need much larger amounts of fats and carbohydrates. Micronutrient deficiencies may result in numerous problems, many of which affect some aspect of behavior. Selected micronutrients were described by Benton (2008b); see Table 7.6 for a summary of his paper.

From a practical standpoint, following the advice of the U.S. Dietary Guidelines (Table 7.2) regarding choice of food groups (fruits, vegetables, and whole grains) and choosing foods with minimal amounts of added sugar will ensure a diet that provides an ample amount of vitamin A, folate, and iron and have a low GI. In ad-

7.5

The Influence of Children's Diet on Their Cognition and Behavior

	THEORETICAL MECHANISM	OUTCOME/IMPLICATION
Meals and Cognition	Newborns spend about 44% of basal energy for brain functioning. The brain continues to use a high rate of glucose until about age 9 years.	To promote mental alertness and cognitive functioning, adequate caloric intake is required. Infants need frequent feedings. During childhood, 3 meals and 2–3 snacks per day spaced about 3 hours apart are desirable.
Carbohydrate and Breakfast	Omission of breakfast, especially among children at nutritional risk, interferes with academic performance due to low glucose available to the brain. Breakfast foods with low glycemic index, which are digested and absorbed slowly, are associated with improved academic outcomes.	Breakfast foods should have a low glycemic index. Good choices are whole-grain breads and cereal; protein sources such as eggs, nuts, butters, or cheese; and dairy products. This will ensure prolonged glucose availability to the brain and a reduced decline in attention during the morning. Breakfast should contain 210 to 270 calories.
Snacking	Snacking decreases fatigue and sustains attention. Chocolate has been shown to decrease tiredness in adults. Midmorning snacks and mid-afternoon snacks improve concentration and decrease frustration.	Between-meal snacks that provide a moderate amount of calories (< 200) should be provided to children and adolescents, especially if a small breakfast (< 200 calories) was eaten.
Glucose to Brain	When faced with cognitive demands, brain glucose needs increase.	Ensure that a meal or snack with ample available carbohydrate is provided before tests, homework, or other activities that require concentration and reasoning.
Sucrose	Meta-analyses of double-blind studies on the impact of sucrose and behavior have produced no evidence that it has an adverse effect. Sucrose, a refined white “table sugar,” is an “empty calorie” food. In excess, sucrose may “dilute” the diet by displacing foods that have natural vitamins and minerals.	To ensure optimal intake of the essential nutrients (e.g., vitamins, minerals, and protein), avoid foods that are high in added sugars such as soda, candy, and processed baked goods. Follow the U.S. Dietary Guidelines recommendations to consume ample fruits, vegetables, and unprocessed or minimally processed grains.

From “The Influence of Children's Diet on Their Cognition and Behavior,” by D. Benton, 2008a, *European Journal of Nutrition*, 47 (Suppl. 3), 25–37.

Cognitive and Behavioral Problems and Food Sources of Selected Micronutrients

MICRONUTRIENT	COGNITIVE AND BEHAVIORAL CONCERNS	FOOD SOURCES
Vitamin A	In retinoid form, it controls differentiation of neurons. It may have a role in memory, sleep, depression, Parkinson's disease, and Alzheimer's disease. Rat studies have found retinoid receptors in the hippocampus, an area of the brain important for memory. Vitamin A deficiency disrupts memory.	As retinol: liver, eggs, cheese, butter As beta-carotene: carrots, pumpkin, winter and acorn squashes
Iodine	A lack of iodine during the first and second trimesters of gestation, a critical period in brain development, is associated with cretinism and a reduction in intellectual ability. Deficiency is associated with information processing, fine motor skills, and visual problem solving. Deficiency linked to attention-deficit/hyperactivity disorder.	Iodized salt, seafood, soybeans, spinach, turnip greens, lima beans, mushrooms
Iron	Iron-deficit anemia is associated with general tiredness, lowered mood, and an inability to concentrate and remember. Low iron status adversely influences psychological functioning, which is believed to result from decreased activity of iron-containing enzymes in the brain.	Liver, red meats, eggs, dark green leafy vegetables, legumes, whole grains, and enriched food products
Zinc	Zinc is found in high levels in the brain, where it plays both structural and functional roles. In juvenile monkeys, zinc deficiency was associated with reduced activity and poor memory and attention. Zinc deprivation increases emotionality, decreases appetite, reduces activity, and disrupts memory and attention.	Oysters and other seafood, liver, meats, eggs, milk, and whole-grain products
Folate	Folate status during pregnancy may influence human brain development. Infants born to mothers with severe folate deficiency during pregnancy showed abnormal or delayed development.	Fortified grain products, leafy green vegetables, legumes, liver, okra, and asparagus
Vitamin B-12	Marginal vitamin B12 status has been linked to impaired cognitive functioning. Degree of B-12 deficiency has been linked to nonverbal measure of intelligence. Deficiency can cause brain damage in infants, irritability, anorexia, and failure to thrive associated with marked developmental regression and poor brain growth.	Only found in animal products such as beef, fish, poultry, milk and cheese

From "The Influence of Children's Diet on Their Cognition and Behavior," by D. Benton, 2008a, *European Journal of Nutrition*, 47(Suppl. 3), 25–37.

dition, it is important to adhere to the dietary fat recommendations of limiting saturated and trans-fatty acids while increasing fats from nuts, seeds, and fatty fish, which will increase the omega-3 fatty acid intake. While the Dietary Guidelines were originally developed to reduce the rate of cardiovascular disease among Americans, it is becoming evident that taking heed of their advice may also impact behavior.

INTEGRATING NUTRITION INTO PSYCHOLOGICAL ASSESSMENTS AND RECOMMENDATIONS

Nutritional status does affect behavior. Nutritional status should be considered when a psychologist is working with patients in a clinical setting, as well as in research. In the clinical setting, asking a few key nutrition-related questions (Table 7.7) in the initial interview will give the clinician an idea of the individual's general dietary profile. For patients with suspected nutrition problems, the psychologist should refer to a registered dietitian for a complete nutritional assessment. All hospitals employ registered dietitians, and many do outpatient assessments and counseling. The American Dietetic Association (<http://www.eatright.org>) has a list of registered dietitians by state and their contact information.

When research is being conducted, nutrition factors should be considered. Ideally, a registered dietitian with experience in research should be a part of the research team. Since nutrition is implicated in various aspects of behavior, at minimum, the general eating habits of the study population and the season of the year during which data are collected should be considered. For example, if the study population is from a coastal area, one may assume that more seafood will be consumed. Or if the study is conducted during the summer, subjects will have more fruits and vegetables, providing more vitamins in the diet. If dietary intake is a major part of the study, a more detailed nutritional assessment that includes, at minimum, a dietary assessment such as a 24-hour-food recall or food frequency should be included.

As mentioned earlier, two centers that assist in nutritional assessments are the Arizona Diet, Behavioral, and Quality of Life Assessment Center (<http://www.azdiet-behavior.azcc.arizona.edu/index.html>) and the Fred Hutchinson Cancer Research Center (http://www.flhrc.org/science/shared_resources/nutrition). In addition to having dietary assessment forms, other services they provide include:

Suggested Nutrition-Related Questions to Include in the Initial Psychological Assessment

NUTRITION-RELATED QUESTION	IMPLICATION IF ANSWERED YES
(1) Do you eat fewer than 2 meals per day?	The individual may experience periods of hypoglycemia and lowered nutrient intake.
(2) Do you eat fried fast-foods more than 3 times each week?	This indicates excessive trans fat and saturated fat intake from fast foods. Also, intake of these foods may displace nutrient-dense foods.
(3) Do you eat fewer than 3 servings of fruits and/or vegetables—not including French fries or chips?	Low intake of key vitamins and minerals (vitamins A, C, foliate, iron, and zinc) may interfere with normal metabolic processes.
(4) Without trying to, have you lost or gained 10 pounds in the last 6 months?	Unintended weight gain or loss is often a sign of an underlying disease or condition, which may affect nutrient utilization.
(5) Do you ever lack money to buy the foods you need?	Nutrient-dense foods are more expensive than foods with lower nutrient density, which decreases essential nutrient intake.
(6) Do you have an illness or condition that made you change the kind and/or amount of food you eat?	Recent changes in health status may affect diet quality, leading to reduced intake of essential nutrients.
<i>Note:</i> If patient answers “yes” to these, a referral to a registered dietitian is recommended for nutritional counseling.	

- Development of standardized, customized behavioral and food frequency questionnaires to meet specific research objectives

- Consultation for design of nutrition, behavioral, and quality-of-life assessments and interventions
- Training and certification of dietary interviewers
- Collection of 24-hour dietary recalls by telephone or in person
- Nutrient assessment of 24-hour recalls, dietary intake records, food frequency questionnaires, and recipes/ menus
- Behavioral assessment of questionnaires on physical activity, health habits, smoking behaviors, and sexual practices
- Statistical summarization and analysis

Exercise in Preventive Behavioral Medicine: The Disconnected Values Model

Mark H. Anshel

For many years exercise has been known to have therapeutic value, for example, improving selected personal dispositions and mental health. Improving the rate at which individuals engage in exercise and other forms of physical activity, however, has proved to be very difficult. Approximately 50% of exercisers drop out of organized programs within the first 6 months of beginning the program. New innovative approaches are needed to promote exercise participation and adherence. The purpose of this chapter is to introduce a novel approach to changing health behavior, with a particular focus on promoting exercise behavior, called the disconnected values model (DVM; Anshel & Kang, 2007a, 2007b). The DVM does not require that the practitioner be a licensed psychologist and therefore may be applied by behavioral medicine practitioners and consultants. The goal of this model is to assist clients to identify a disconnect, or inconsistency, between one or more of their unhealthy habits and their deepest values (e.g., health, family, performance excellence). Health behavior change is far more likely if the client acknowledges that the disconnect is unacceptable, given the short-term costs and long-term consequences of the present situation. The next step is to generate and carry out an action plan that will ostensibly replace the unhealthy

negative habit with healthier positive routines. In addition to reviewing selected studies that lend credence to the DVM, this chapter details a case study in which a university faculty member participated in an intervention based on the DVM that resulted in marked changes in fitness and blood lipids. Implications for practitioners and future research on testing the model's efficacy are discussed.

EXERCISE THERAPY: PREVENTIVE BEHAVIORAL MEDICINE

Attempts to encourage exercise behavior have been extensive in recent years. However, the use of effective interventions in promoting exercise behavior by medical practitioners has been relatively ignored in the extant behavioral medicine literature. Interventions have been only moderately successful in promoting and maintaining exercise behavior and often require that the practitioner be a licensed psychologist to examine the underlying causes of resistance to developing an exercise habit (Buckworth & Dishman, 2002).

THE PROBLEM

The consequences of the prevalence of inactivity and overweight include widespread serious deterioration of health and quality of life in the United States and around the world. For example, recent studies indicate that 63% of U.S. men and women are overweight, and about 33% are classified as obese. Approximately 60%–70% of adults who begin an exercise program will quit within 6–9 months, despite the widespread belief (held by 82% of adults) that exercise is beneficial to good health (Marcus, King, Bock, Borrelli, & Clark, 1998). The resulting deterioration in health also has long-term consequences. The combination of obesity and a sedentary lifestyle, leading to the widespread onset of types 1 and 2 diabetes and hypertension, is the likely culprit (Nestle & Jacobson, 2000). However, as Nestle and Jacobson recognize, while the causes of obesity are well known, the antecedent habits that cause obesity, such as poor nutrition and lack of exercise, are very difficult to change.

The problem of non-adherence to healthy habits is not new in the health psychology literature. For example, Sackett (1976) found that scheduled appointments for treatment are missed 20%–50% of the time, and that about 50% of patients are remiss in taking their medications as prescribed by their physician. After 6 months, other health-related changes (e.g., smoking cessation, dietary restrictions, weight control strategies) have an adherence rate of less than 50%. While existing theories and models have provided a coherent framework with which to provide explanations for descriptions and predictions of exercise behavior, their application for increasing exercise behavior has been met with equivocal success (Buckworth & Dishman, 2002). It is necessary to briefly address limitations of selected intervention research to justify a new applied intervention model that promotes involvement in exercise.

LIMITATIONS OF EXERCISE INTERVENTION RESEARCH

The amount of outcome variance found in studies testing the efficacy of exercise interventions has rarely been above 30% (Baranowski, Anderson, & Carmack, 1998). Dishman and Buckworth (1997) conducted a meta-analysis of 127 studies and 14 dissertations to determine the effectiveness of interventions intended to enhance exercise adherence in a healthy population. They reported that only about 20% of the studies included

a follow-up to the intervention. Typically, increased physical activity or fitness associated with the interventions diminished with time after the end of the intervention. These results persisted regardless of age, gender, and race. Effects were better under conditions of low to moderate intensity than for strength or aerobic training.

Selected limitations of the extant exercise intervention literature have been reviewed by Prochaska, Spring, and Nigg (2008); Glasgow, Klesges, Dzewaltowski, Bull, and Estabrooks (2004); Buckworth and Dishman (2002); Dishman and Buckworth (1997); Morgan (1997); and Sallis and Owen (1999), among others. For example, Buckworth and Dishman lament the absence of a theoretical framework or model with which to examine the efficacy of an intervention intended to promote exercise participation and adherence. They correctly conclude that “without a theoretical framework, the choice of variables cannot be well justified and the ability to interpret results is limited” (Dishman & Buckworth, 1997, p. 252). In addition, Dishman (1991) asserts that the majority of early exercise intervention research has relied on one-dimensional techniques and a small sample size of highly selected participants (e.g., clinical populations, individuals already engaged in a specific program). Thus, the generalizability of findings from these studies to the community would not be feasible.

Another reason that may explain the paucity of exercise intervention effectiveness is that strategies and programs are often imposed on the individual: researchers have not controlled for the exerciser’s motives and rationale for and personal commitment to beginning and maintaining an exercise program. Researchers often assume that the person *desires* a change in behavior (Buckworth & Dishman, 2002; Marcus & Stanton, 1993). Consequently, goals for behavior change have traditionally been imposed on the individual by the researcher or clinician rather than self-determined by the exerciser. Along these lines, participants often lack of personal involvement in voluntarily choosing and committing to the type and schedule of exercise involvement, a strategy referred to as perceived choice (Markland, 1999), or what Ajzen (1985) calls perceived behavioral control. In typical exercise adherence studies, exercisers are required to attend group sessions, often at specific times, performing predetermined exercise routines.

Another limitation is that research has addressed specific cognitive (e.g., positive self-talk, imagery, cognitive appraisal) and behavioral strategies (e.g., goal setting, music, social support) rather than providing a coherent intervention program. In addition, intervention research has focused on outcomes (e.g., changes in attitude toward exercise and level of exercise adherence)

rather than the mechanisms and processes by which changes to exercise-related attitudes and behavior occur. For instance, the provision of educational materials, personal coaching, and social support, either combined or separately, may improve adherence—temporarily, at least (Sallis & Owen, 1999).

In their extensive critique of previous intervention research, Buckworth and Dishman (2002) claim that “many interventions have been developed without a theoretical model or with only selected components of a model.” In addition, “interventions are typically not tested to see whether they change the variables they are designed to change, or whether the target variables are actually responsible for changes in the outcome variable” (p. 252). As Glasgow et al. (2004) have concluded from their related literature review, “it is well documented that the results of most behavioral and health promotion studies have not been translated into practice” (p. 3).

One mechanism that is likely to lead to health and exercise behavior change is what Oldridge (2001) refers to as “regimen factors” to improve adherence to any activity, although he refers to exercise. Strategies that are implemented as an integral part of one’s daily routine promote adherence to health behaviors. In particular, he suggests “keeping the regimen straightforward, providing clear instructions and periodic checks, promoting good communication with the patient, and reinforcing their accomplishments” (p. 322). Oldridge contends that adherence strategies are seldom very effective on their own. Thus, an intervention model is needed that incorporates these suggestions.

One approach to health behavior change involve examining the costs and consequences of practicing unhealthy behaviors. For instance, Strelan and Boeckmann (2003) suggest that practitioners can facilitate an athlete’s decision not to ingest banned drugs by helping him or her acknowledge the benefits and costs of this unhealthy behavior in their drugs in sport deterrence model. Only when the athlete concludes that the costs of drug use outweigh its benefits will there be compliance. As the authors contend, there are benefits to every negative habit, such as drug taking, or else the athlete would not sustain it. In addition, recognizing the benefits of the negative habit lends credibility to the process of determining their costs. Factors from the drugs in sport deterrence model can be used to describe interventions to promote exercise behavior, in which a person determines the benefits and costs of exercising and maintaining an active lifestyle, as opposed to not exercising and remaining sedentary.

The benefits of not exercising, for example, include having time to do other things, and avoiding physical

discomfort, costs of exercise apparel, exercise equipment, and a fitness club membership, as well as feelings of anxiety, embarrassment, or self-consciousness when exercising in the presence of others.

Not exercising, however, has several costs to one’s quality of life and health. For example, the costs of not exercising include poorer health, weight gain, heightened stress and other negative mood states, poor physical physique and unattractiveness, and poorer quality of life. Weighing the costs and consequences of an action that may be considered unhealthy, and then comparing these factors with the benefits of maintaining the unhealthy action, is not enough to result in behavior change. Individuals need to conclude that their actions are both inappropriate and inconsistent with their core beliefs, also referred to as their values.

THE IMPORTANCE OF VALUES FOR EXERCISE INTERVENTIONS

Perhaps the most commonly neglected research area related to behavior change is the contrast between a person’s lack of an exercise habit and his or her values and beliefs about what is important in life (Dunn, Andersen, & Jakicic, 1998). The inconsistency between values such as health, family, and performance excellence and a sedentary lifestyle provides an incentive to change exercise habits. Values, then, form a relevant component of the present model.

Values are core beliefs that guide behavior, provide impetus for motivating behavior, and provide standards against which we assess behavior (Rokeach, 1973). Values are highly relevant to establishing a person’s individuality and help us understand behavior. For example, as Rokeach contends, a person who values health will tend to develop daily rituals and long-term habits that enhance health and general well-being. Hogan and Mookherjee (1981) describe values as “one of the most distinguishing characteristics motivating human beings; the likely effects of values on human behavior, beliefs, and attitudes are indisputable” (p. 29).

Crace and Hardy (1997) developed an 8-step values-based intervention to enhance sports team building that has implications for the model I will discuss in this chapter. Briefly, their model involves (1) helping athletes understand the importance of individual differences for enhanced performance (i.e., differences in team members’ personalities are viewed as normal), (2) assessing individual differences in the athletes’ own goals and values, (3) understanding the interactions

between values and life roles (i.e., values are identified within each life role), (4) identifying and understanding the primary team values (i.e., values shared by team members), (5) identifying ways in which values can enhance or inhibit team cohesion (e.g., the value of responsibility can improve commitment to team success but can also result in an individual being overwhelmed by the lack of responsibility among selected teammates, resulting in mental fatigue and guilt), (6) developing an action plan to improve compatibility of the athletes' and the team's values with the ultimate purpose of improving attainment of team values, (7) performing similar strategies with the team's coaches, and finally (8) scheduling follow-up meetings with the athletes and coaches to discuss the effectiveness of the team-building program.

The strength of their model is the recognition that a person's values guide his or her behavior, and that sharing values with others has a strong effect on the commitment to sacrifice personal, self-serving needs for the benefit of others, in this case, the team. One important implication of their model in an exercise setting is that a person's values may or may not be compatible with the values of family members or an employer. Crace and Hardy (1997) recognize the need to enhance the values among these parties to help the person reach optimal performance. However, there are several components of this model that limit its effectiveness in promoting exercise behavior, not the least of which is detecting discord between the individual's values and the negative habit of inactivity. This is particularly relevant when one is addressing the values of health and happiness, two fundamental tenets of quality of life.

Values are more central determinants of behavior than are interests and attitudes (Super, 1995), the latter of which are more situational and derived from a core set of values. Thus, a plethora of interests and attitudes are derived from a relatively reduced number of values. In addition, interests, attitudes, and needs are transitory and, once satiated, may not influence behavior. Values, on the other hand, are almost always firmly entrenched and stable, and therefore, transcend situations and guide behavior over a long period of time.

While research on values in relation to exercise behavior is lacking, it is likely that values predict behavior (Brown & Crace, 1996; Hogan & Mookherjee, 1981). Individuals who value health, therefore, are more likely to engage in behaviors that enhance their health. If the value of family is an important value, then predictably, more time and effort will be devoted to enhancing family relationships and well-being. However, if health forms part of a person's value system, and that indi-

vidual's behaviors are inconsistent with this value (e.g., he or she does not exercise, has poor nutrition, does not get enough sleep), the link between value and behavior is disconnected. This disconnect forms an important segment of the current model to enhance exercise behavior.

The extent to which individuals value their health, as opposed to how much effort and time they spend on health-related behaviors, is one indication of a disconnect between negative habits (e.g., exercise, poor nutrition) and their values, when these values include health (Loehr & Schwartz, 2003). There may be a high degree of consistency between the how much importance the people say they accord to their health and the time they invest in it, if they are regular exercisers. There is a large discrepancy, however, among persons who state that health is an important value yet lead a sedentary lifestyle. That is, individuals may value their health; however, the amount of time they spend improving and maintaining their health may not reflect this value. To Loehr and Schwartz, this is called a disconnect and forms the basis for helping individuals change their exercise behavior.

The individual may conclude that the benefits of remaining sedentary and not exercising (e.g., having more time to do other things, not experiencing the discomfort associated with vigorous exercise) are greater than the costs of remaining sedentary (e.g., weight gain, poorer health, reduced life span). Only when these costs are greater than the benefits and the person perceives the costs to be unacceptable will there be the proper "ignition" to begin and maintain an exercise habit.

THE DISCONNECTED VALUES MODEL

The process of behavior change is challenging because habits and routines, in this case, lack of regular exercise, are firmly entrenched in the person's lifestyle (Ockene, 2001). Attempting to increase exercise behavior is particularly difficult because people often must contend with an array of long-held feelings and attitudes that may reflect negative previous experiences (e.g., the physical education teacher who used exercise as a form of discipline, a former athlete's burnout from too much physical training, injury from previous exercise attempts). Furthermore, vigorous exercise requires effort and some degree of physical discomfort if one wishes to obtain the well-known benefits. The degree of discomfort, often measured as "ratings of perceived exertion" (Borg, 1998), is directly related to several characteristics, such as current body weight, the extent of

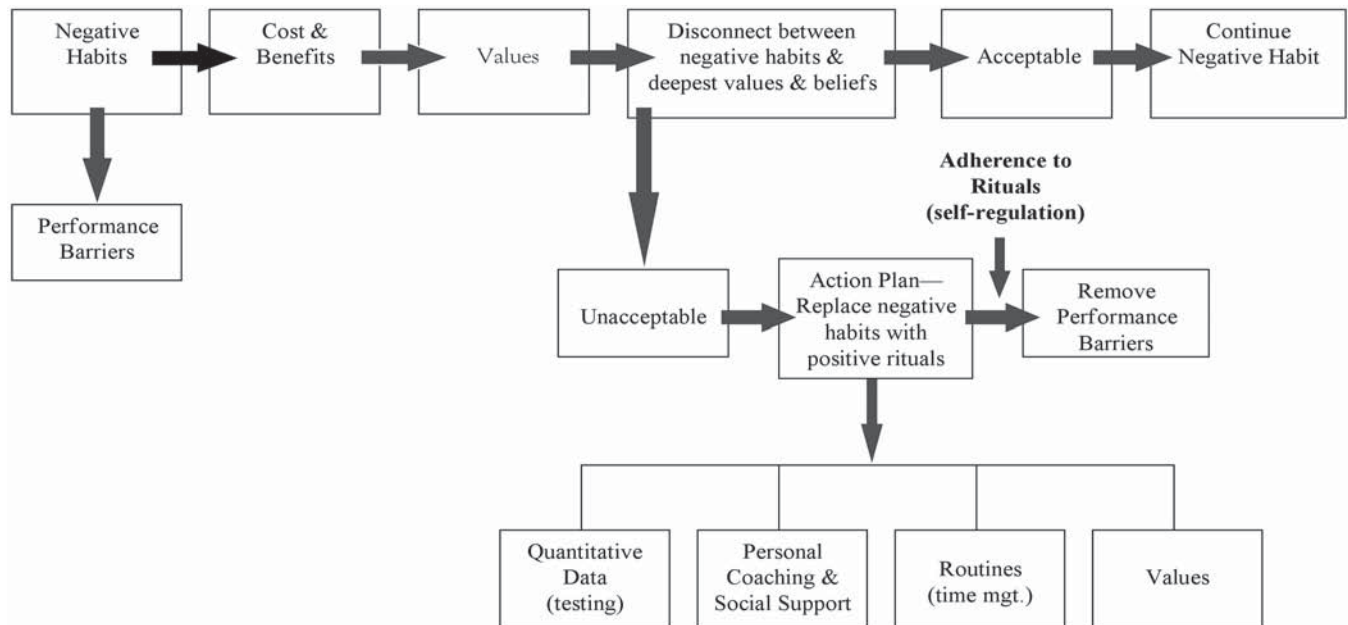

Figure 8.1 The disconnected values model.

poor fitness, and degree to which the person's lifestyle has been sedentary. Thus, a new approach for effective intervention outcomes is needed.

The DVM is predicated on two postulates that define self-motivated behavior that have strong implications for promoting exercise behavior, which is often missing from existing exercise intervention research. First, self-motivated behavior reflects a person's deepest values and beliefs, that is, the power of purpose (Loehr & Schwartz, 2003). Purpose prompts a desire to become fully engaged in activities that "really matter" in meeting personal goals and future aspirations. Second, the primary motivators of normal human behavior are (1) identifying a deeply held set of values, (2) living a life consistent with those values, and (3) consistently holding ourselves accountable to them. Ostensibly, then, an individual whose values include health, family, and performance excellence—examples of three common values—should be motivated to exercise because it is consistent with these values. A deeper sense of purpose involves shifting one's attention from fulfilling one's own needs and desires to serving and meeting the needs of others. An individual who values family, for instance, realizes that by exercising, he or she will have more energy and lead a higher quality of life in meeting the needs of family members. Perhaps, then, the self-motivated drive to develop an exercise habit rests, at least in part, on recognizing the incon-

sistency between one's negative habits (i.e., lack of regular exercise) and one's values and then instituting a positive new habit of exercise that is strongly connected to one's values. As Loehr and Schwartz (2003) conclude, "deeply held values fuel the energy on which purpose is built" (p. 140). The DVM, the foundation of which is acting in a manner consistent with one's values, is illustrated in Figure 8.1.

Theoretical Foundations of the DVM

The process of health behavior change that is manifested in the DVM is predicated primarily on two theoretical frameworks: motivational interviewing (MI) and Festinger's (1957) cognitive dissonance theory.

Hecht, Borrelli, Breger, DeFrancesco, Ernst, and Resnicow (2005) and Miller and Rollnick (2002) describe MI as a client-centered method intended to enhance intrinsic motivation for health behavior change by way of three essential functions. First, the client collaborates with the interviewer to create a safe, supportive, and nonjudgmental environment for initiating a change in habit. Second, the interviewer explores with the client reasons for and against behavior change—its benefits and costs—in order to resolve ambivalence. Third, the interviewer helps the client develop a sense of autonomy (responsibility) for changing behavior. Thus, the client decides if change will occur and, if so, how and when.

As explained by Miller and Rollnick (2002), MI is best described by four postulates that reveal the mechanisms by which MI functions as a system for behavior change in the consulting process. The first postulate is that MI is client or person centered in that it focuses on the concerns and perspectives of the individual. It does not focus on teaching new coping skills, reshaping cognitions, or reexamining the past. The focus is on the person's current concerns and interests, and exploring discrepancies between the person's own experiences and values. The second postulate is that MI intentionally addresses specific changes in behavior. The client and interviewer exchange views about the most desirable and realistic changes, and the interviewer addresses possible barriers to change.

The third postulate is that MI is a method of communication rather than a set of techniques. MI is a collaborative technique; that is, it is "a facilitative approach to communication that evokes natural change" (Miller & Rollnick, 2002, p. 25). MI focuses on exploring and resolving ambivalence as a key to elicit change. MI does not attempt to impose change; it is not coercive. Changes must be in the person's inherent interest and must be relevant to the person's own values and concerns. Finally, the focus of MI is eliciting the person's intrinsic motivation for change; change is not imposed. The goals of MI are to increase the person's motivation to instigate behavior change and to promote long-term adherence to new, desirable behaviors.

Components of MI are collaboration, evocation, and autonomy, each of which was followed in this study. Collaboration involves encouraging client self-awareness about his or her real world, which often goes unnoticed by the client. The DVM enacts a similar strategy by way of two processes: (1) pointing out objective evidence of current or potential health problems based on test data (e.g., abnormal lipids profile scores, poor fitness test results) and (2) using the client's own examples of performance barriers and sample negative habits that likely contribute to those barriers. In the evocation stage, motivation for change is intrinsic; health behavior change involves drawing on the client's own perceptions, goals, and values. It is assumed that the client has the proper knowledge, insights, and skills necessary for change. Along these lines, the DVM requires clients to acknowledge the benefits, costs, and long-term consequences of their negative, unhealthy habits, and to also detect, by way of a self-report inventory, inconsistencies between their poor habits and their values. Finally, in the autonomy stage, the client's capacity for self-direction is affirmed; the client makes informed choices about future directions and reaffirms his or her commitment

to future behavior changes. The DVM asks the client to commit to an action plan in which the client commits to a new set of routines that are scheduled and supported by the client's significant others.

Perhaps the misalignment between one's behaviors and one's values is best dealt with by Festinger's (1957) cognitive dissonance theory. The theory posits a tendency for individuals to seek consistency among their cognitions (i.e., beliefs, personal views, emotions, values). An inconsistency between attitudes and behaviors (dissonance) results in an individual's drive to change the attitude to accommodate the behavior. The most important factors that influence this drive for change are the number of dissonant beliefs and the importance a person attaches to each belief. For example, beliefs about, or the importance of, family may be dissonant with ignoring family members, not taking the time to mentor children, or not developing positive relationships. Dissonance may be reduced or eliminated either through the reduction of the importance of the conflicting beliefs, acquisition of new beliefs that change the balance, or removal of the conflicting attitude or behavior. While cognitive dissonance theory provides a valid theoretical foundation for the current model, the DVM goes beyond the recognition of dissonance by asking the individual to acknowledge the costs and long-term consequences of his or her negative habits and to develop a self-regulation action plan that carries out cognitive-behavioral strategies to replace the negative habit with positive new rituals.

The DVM requires that the client become an active processor of information by becoming aware of limitations in his or her job performance, happiness, and quality of life; agreeing that his or her unhealthy habits are the cause of these limitations; acknowledging the costs and long-term consequences of these habits; determining personal goals that will overcome current limitations; and generating an action plan that replaces negative habits with positive routines.

Negative Habits

The model begins by acknowledging the existence of negative habits, defined as thoughts, emotions, or tasks that the person experiences regularly and acknowledges to be unhealthy or not in his or her best interests yet remain under the individual's control. Despite one's ability to prevent or stop these negative habits, one continues to experience them. In this example, not exercising and poor nutrition are negative habits that need changing. Quality of life suffers.

The primary reason individuals engage in negative habits is because the perceived benefits of maintaining the habit outweigh its costs and long-term consequences. A habit does not exist without benefits. For example, the negative habit of exhibiting anger in response to frustration has the perceived benefits of prompting action, allowing one to maintain situational control, and permitting the emotional release of unpleasant feelings. The costs of anger (e.g., alienating others, poor social relationships, heightened stress) and long-term consequences (e.g., developing heart disease and hypertension, lack of respect and trust by others) are either not acknowledged or perceived as less important to the person's short-term goals. Under these conditions, the negative habit persists.

Performance Barriers

A performance barrier is operationally defined as a persistent thought, emotion, or action that compromises and creates obstacles to high-quality performance (Dunn et al., 1998). Whether these barriers are actual (e.g., injury, anger) or perceived (e.g., time restraints, discomfort, anxiety), they are always controllable and thus changeable. For instance, the emotional barrier of anxiety (i.e., worry) can be controlled when one addresses the source of concern and develops adaptation strategies that overcome these thoughts. A person who is uncomfortable and self-conscious about exercising among younger, fitter, thinner individuals at a fitness facility can focus on his or her exercise regimen, while ignoring others in the room. A person who has time restraints can develop time management strategies and use social support from significant others to allow for exercise time.

The importance of performance barriers in the DVM is their root cause—negative habits. These behavioral tendencies, or habits, are labeled negative because (1) it is generally acknowledged that they have a deleterious effect on the person's quality of life, or some aspect of it, and (2) continued expression of the negative habits is directly linked to problems and limitations in work performance. For example, the negative physical habit “lack of exercise” will lead to low energy and fatigue. The emotional negative habit of persistent anxiety will lead to the negative habit of poor (slow, inaccurate) decision making. The negative physical habit of poor work-life balance results in poor relationships with family. One function of the model, then, is to help the client detect negative habits and how they lead to undesirable performance in various aspects of the client's life, not only health. The primary goal at this stage, after nega-

tive habits have been associated with performance limitations, is to begin the process of examining the reasons for, or benefits of, maintaining these negative habits, in this case, lack of exercise.

Benefits and Consequences of Negative Habits

There are benefits to each of our negative habits. If there were no benefits, the negative habit would not continue. As discussed earlier, the benefits of not exercising, for example, include having more time to do other things, not experiencing the discomfort of physical exertion, and not having to spend money on things like fitness club memberships and exercise clothing.

There are, of course, several short-term costs and long-term consequences to not exercising.

These include reduced fitness, weight gain, and higher stress and anxiety (both of which can be reduced with exercise). The long-term consequences of these costs include poor physical and mental health, reduced quality of life, and, in some cases, shorter life span. Are these costs acceptable? If they are, then the negative habit of not exercising and maintaining a sedentary lifestyle will likely continue. However, if the costs are far greater than the benefits, *and* the person concludes that these costs are unacceptable, then a change in behavior is far more likely. Perhaps the most important factor in changing health behavior in the model is linking the costs of inactivity to the person's deepest values and beliefs.

Determining One's Deepest Values and Beliefs

The DVM includes a component virtually ignored by researchers—providing intervention content that provides a sense of purpose, that is, “the energy derived from connecting to deeply held values and a purpose beyond one's self-interest” (Loehr & Schwartz, 2003, p. 131). The authors explain self-destructive behaviors and negative habits (e.g., poor nutrition, lack of exercise, high stress) as reflecting a “lack of . . . firm beliefs and compelling values (that are) easily buffeted by the prevailing winds. If we lack a strong sense of purpose (i.e., what really matters to us; our passion) we cannot hold our ground when we are challenged by life's inevitable storms” (p. 133).

If you were to give individuals a list of values—what they consider to be their beliefs about what is really important to them—and then ask them to rank

these values, they would probably rank health and family near the top. Sample values include integrity, happiness, honesty, character, excellence, commitment, and concern for others. Perhaps the values that are most commonly selected by clients are health, family, faith, and kindness.

In summary, the decision to begin and maintain an exercise program is more likely if (1) a person acknowledges that the costs and long-term consequences of a negative habit are greater than the benefits, (2) that these costs run counter to the person's deepest values and beliefs about what is important, and finally (3) that the discrepancy between their negative habits and their values is unacceptable. Thus, behavior change is more likely to be permanent when the client concludes that life satisfaction is linked to behaving in a way that is consistent with his or her deepest values.

Establishing a Disconnect

To help clients detect an inconsistency between their values and their negative (self-destructive) habits, sport psychology consultants might ask non-exercising clients, "To what extent are your values consistent with your actions? If you value your health, for instance, do you have habits that are not good for you and, therefore, inconsistent with your values? What about your family? Do you value your spouse, children, or parents? If you lead a sedentary lifestyle and are not involved in a program of exercise, yet one of your deepest values is maintain good health, to what extent is your value inconsistent with your behavior? Is there a disconnect between your beliefs about good health and your unhealthy behavioral patterns?" We will now describe the most common models in exercise psychology and then provide ways in which each can be applied in exercise settings.

Acceptability of the Disconnect

If health behavior change is to occur, two processes are needed. First, individuals must acknowledge that the negative habit (e.g., not exercising regularly) is inconsistent with their most important values. Second, they must conclude that this disconnect is not acceptable. "Is it OK with you that your decision not to exercise regularly is inconsistent with your values of health, family, and faith, especially after knowing the costs and long-term consequences of this negative habit?" If they respond that the disconnect is acceptable, which is entirely possible, then no change in their unhealthy

habit will likely occur. Then the practitioner must identify another disconnect between negative habits and values that the individual has listed. Only when the person finds the disconnect unacceptable will he or she commit to behavior change and agree to carry out an action plan.

Developing a Self-Regulation Action Plan

The person's decision to initiate an exercise program is followed by development of a detailed self-regulation action plan. This involves determining how the individual will develop a habit of regular exercise during the week. Additional changes related to improved sleep or eating habits are also possible; however, it is important not to make too many changes in unhealthy habits at one time (Loehr & Schwartz, 2003).

The action plan primarily involves of three factors that will markedly enhance the individual's *permanent* commitment to regular exercise: (1) a specific time within a 24-hour period for exercise engagement; (2) a set of routines that support the exercise habit (e.g., selected thoughts and behaviors in which the individual will engage prior to, during, and following the exercise session; exercising with a friend and promoting other forms of social support; minimizing distractions that will interfere with exercise plans); and (4) linking these specific times and routines to the individual's deepest values and beliefs, thereby removing the existing disconnect. Finally, the practitioner develops a self-regulation action plan consisting of new routines that are built into the client workday. These normally include pre-sleep rituals (e.g., no food or alcohol within an hour of bedtime, planned relaxed activity, positive communication with family members); sleep and waking times; times for exercise, meals, and recovery breaks; times to connect with family/significant others; and other rituals linked to each dimension and the client's values.

Research Support of the DVM

The DVM is not without empirical support. Two studies have examined the model's efficacy in exercise settings. Anshel and Kang (2007a, 2007b) examined the effect of the DVM among university employees in two action studies. In both studies, 100 participants engaged in the DVM as part of their orientation to the 10-week program; this involved use of a workbook and DVD that communicated the model's primary concepts. Clients were also assigned a fitness coach, with whom they met once per week, and also met individu-

ally on one occasion, and in weekly small group sessions, with a registered dietician. Selected measures of fitness and blood lipids were compared at baseline and immediately following the program. Separate MANOVAs showed significant improvement from baseline to post-intervention scores for measures of strength, cardiovascular fitness, and percent body fat ($ps < .001$), while blood lipids were significantly improved. LDL and HDL were markedly lower and higher, respectively. Triglycerides were also reduced markedly on the post-test.

The DVM served as the framework for delivery of the intervention. Among other tasks, participants were asked to identify their negative (i.e., unhealthy) habits then list their values and acknowledge the disconnect between the two lists. For example, several individuals volunteered that they possessed unhealthy eating habits and had not engaged in a habit of regular exercise in many years—contrary to numerous passages in Scripture that support healthy habits, health, family, integrity, honesty, excellence, happiness, and compassion—and yet their values included faith. All participants found at least one disconnect between their decision not to exercise or eat properly and at least one of their values. They also acknowledged that given the costs and consequences of maintaining these negative habits, the disconnects were unacceptable. Participants then voluntarily participated in developing an action plan that included a schedule for exercising and involved developing proper eating and sleeping habits and being more self-aware of their self-destructive behavior patterns. According to post-program survey data, the participants agreed that the costs of the disconnect and their wish to live a longer, healthier life served as a primary source of motivation that fostered adherence to the new routines.

Similar results were obtained in a study of police officers (Anshel & Kang, 2008) in which the officers agreed that their habits of maintaining a sedentary lifestyle and eating too many high-fat foods, especially in large portions, were inconsistent with their values of high-quality job performance and ensuring good health so they can provide for their family. Officers agreed that their relatively high rate of adherence to healthier new routines was linked to DVM program content. While each component of the model has not been directly tested, the DVM has served as the foundation for program content that has resulted in promising results and extraordinary adherence rates and appears to touch a nerve in participants, who, for the first time, are examining the consequences of self-destructive behavioral patterns.

APPLICATION OF THE DVM: A BRIEF CASE STUDY

Sally was a non-smoking 38-year-old married mother of one living in the southeastern United States. She weighed 190 pounds, her percent body fat was 36%, and her waist circumference was 38 inches. Sally's two main problems, perhaps not surprisingly, were the absence of regular (daily) exercise and overeating, particularly large portions within an hour of going to sleep. She admitted to eating of a high-fat, low-fiber diet, not uncommon in the southern United States, and not eating raw vegetables. Two years earlier she joined a fitness club but stopped attending the facility after four visits. She claimed to have started exercise programs on four previous occasions in recent years and to have started "more diets than I can count."

With respect to exercise, she claimed that cardiovascular exercise is very uncomfortable, particularly for her arthritic knees. She had not received fitness coaching, however, on ways to improve cardiovascular fitness through the use of a stationary bicycle, which, she acknowledged, would place minimal physical stress on her lower limbs. Her goals were to lose weight (fat), increase muscular strength, and have more energy for her family, especially after coming home from work. She knew that her medical problems will worsen as she ages. In addition, Sally had strong religious beliefs and felt she was not living a life consistent with Scripture, which pontificates the virtues of a healthy lifestyle.

Two coaches were involved in Sally's 10-week program: a fitness coach employed at a local fitness club, and a registered dietician. The fitness coach provided fitness tests (e.g., submax VO_2 , upper and lower body strength, percent body fat, blood pressure, waist circumference) and then prescribed a fitness program based on test results. The coach then worked with her each week on improving both her strength and cardiovascular conditioning.

The registered dietician recorded Sally's current diet and helped her make proper food choices, keeping in mind her eating preferences, much of them less than nutritional. In addition, a blood test revealing her lipids profile served two purposes: it (1) provided data that acted as an incentive to improve healthy behavioral patterns and (2) served as a baseline measure against which to compare post-program test scores. The fitness and blood tests were conducted within a week before and immediately after the program.

The program began by introducing Sally to concepts in the DVM in both written and verbal forms.

Six steps ensued. First, Sally was asked to develop a mission statement about the intended outcomes of the program. Loehr (2007) uses the concept of “ultimate mission” to reflect “the thing that continually renews your spirit . . . the indomitable force that moves you to action when nothing else can” (pp. 43–44). Sally was asked to indicate the most important goals she wanted and needed to achieve during her lifetime (e.g., “What makes your life worth living?” “In what areas of your life must you truly be extraordinary to fulfill your destiny?”). Her answers included serving God (or Jesus), following Scripture, being an extraordinary mother and wife, performing work at the highest level, being a leader in the community, or serving as a role model or mentor to others.

The second task was to identify the negative habits that she felt most impaired her quality of life, energy, and professional career. In order to understand why she maintained those undesirable habits, she listed their benefits. This is the model’s cost-benefit tradeoff segment. The benefits of eating a large bowl of ice cream just before bedtime almost nightly, for example, included enjoying the taste of ice cream, satisfying hunger, and not feeling hungry in the middle of the night, as well as the ice cream’s convenient location (in the freezer) and the lack of preparation involved. Then she listed the costs and long-term consequences of this habit. These included the high fat content of the ice cream and a high number of ingested calories, weight gain, increased level of bad cholesterol and triglycerides, and greater likelihood of heart disease and other diseases. Perhaps the most important disadvantage (consequence) of maintaining this unhealthy habit was the possibility of being deprived of the chance to see her children grow up, graduate from college, and marry, and perhaps the loss of the opportunity to become a grandparent.

In the third segment, Sally was asked to read a list of 40 values and to identify what she considered to be the five most important values, that is, the issues about which she felt most passionate and that most influenced her behaviors. She designated family, faith, health, character, and happiness. She was then asked to make two lists and place them adjacent to each other. The left column consisted of her unhealthy habits (e.g., overeating, eating two fast-food meals a day, avoiding fresh vegetables, not exercising, eating pastry and ice cream before bed). The right column consisted of her values. She was then asked to compare the contents of each list, and to identify areas that were misaligned, or not consistent.

Sally detected four disconnects. She was then asked to contemplate the following statements: “Given the

costs and long-term consequences of this disconnect, do I find the inconsistency between my negative habits and values acceptable? Can I live my life with these disconnects?” We agreed that if she answered yes—that is, that the disconnect was acceptable—she was not likely to change the negative habit, at least in the near future. However, if she concluded that the disconnect was unacceptable, given the costs and consequences of this disconnect, it was likely she was ready to engage in an action plan for replacing the negative habit with positive, healthier routines. Acknowledging the unacceptability of the disconnect, or the costs and consequences of habits incompatible with one’s values, is at the core of the DVM.

Sally concluded that maintaining a disconnected lifestyle was unacceptable and that she was ready to replace unhealthy habits that were depriving him of energy, happiness, and quality of life. For example, she agreed that her ice cream would be consumed at least two hours before bedtime, and only three times per week, not every night. Sally also concluded that living a life more consistent with her values meant continuing to meet with her fitness and nutrition coaches over the coming year, at least until changes in her exercise and eating routines were comfortable and permanent.

Most individual are motivated by numbers (Loehr, 2007). One component of effective interventions for changing health behaviors is testing. Quantitative data allow the individual to compare test scores, ostensibly observing favorable changes on test scores, a reflection of improved health (Anshel & Kang, 2007a, 2007b). Examples of tests include fitness, blood lipids, weight, waist circumference, and body mass index. The results of Sally’s tests, conducted before and immediately after the program, indicated improved lipids profile scores for LDL, HDL, and triglycerides. All scores fell within the normal range. In addition, she obtained improved upper and lower body strength and cardiovascular fitness (i.e., submaximal VO_2 score), reduced her waistline by 4.5 inches, and reduced her percent body fat from 32% to 27%.

In responses to interview questions, Sally indicated experiencing improved energy at work and for family after work, and a generally positive feeling of well-being. A particularly important self-reported finding was her persistence in maintaining both exercise and dietary habits. During the program, Sally attended 24 of 30 (80%) planned exercise sessions, in which she engaged in both cardiovascular and strength training. She stopped eating ice cream and other pastry within an hour of bedtime and maintained several changes in eating habits based on the advice of her nutrition coach

(e.g., eating breakfast, reducing portions at meals, avoiding high-fat foods in the evenings, especially before bedtime). Finally, consistent with the DVM, Sally revealed that a strong motivating factor that compelled her to change her self-destructive habits was her desire to live a life consistent with her value system. She wanted to be a proper role model to her children and improve her relationships with others, including her husband.

Sally was also asked in the interview to indicate the ways in which the program contributed to her decision to initiate and maintain changes in her exercise and eating behaviors. She indicated that four factors facilitated her commitment to changing her habits of non-exercise and poor eating. First, she maintained positive relationships with her two coaches. She established a meaningful relationship with them and respected their skills. Chenoweth (2007) lists respect and admiration of exercise coaches as primary components of coach loyalty and adherence to their advice. Along these lines, Rollnick, Miller, and Butler (2008) assert that establishing good rapport is among the primary objectives of effective interventions because changing behavior begins with establishing trust with a client. For Sally, the coaches provided detailed guidance, instruction, positive and constructive feedback, and emotional support, which encouraged her to maintain progress toward improving her fitness.

Obtaining baseline (pre-test) scores prior to the program was another factor that contributed to Sally's motivation in the program. Sally was "very surprised" and "depressed" (not in the clinical sense) by the extent of her poor blood lipids scores. Her scores indicated premature heart disease, with a very uncertain outcome if there were no changes in her lifestyle. As indicated earlier, quantitative data serve as an important source of motivation to maintain exercise participation (i.e., adherence). Sally's values checklist was a valuable reminder of what was really important to her. Her poor health was inconsistent with her wish to be an effective mother, wife, employee, and devotee to the Lord.

Finally, Sally was an extraordinary client in carrying out her action plan and developing a new set of routines. Her family, especially her husband, was particularly helpful in supporting her mission to break bad habits and have a higher quality of life. While there was no formal measure of quality of life, Sally reported "just feeling better and having more time to do the things that really matter." Her 24-hour time-managed action plan included specific times for exercise, meals, snacks, recovery breaks, and contact with loved ones and colleagues; pre-sleep rituals; and scheduled times for sleep

and waking, at least during the week. Weekends were purposely unstructured with the exception of church attendance, which remained a planned routine. In fact, her church group served as a source of social support, reminding her that improving her health is consistent with Scripture. In this way, Sally linked her exercise and dietary habits to a renewed spiritual life.

IMPLICATIONS AND FUTURE DIRECTIONS

Traditionally, and understandably, research and practice in behavioral medicine have been concerned primarily with the psychological and behavioral factors that influence short-term and long-term health, and the long-term adherence to healthy habits (Ribisl & Humphreys, 1998). The DVM provides an opportunity for behavioral medicine practitioners to address a growing yet unmet need to promote physical activity to an increasingly unhealthy population in the United States and elsewhere.

An important implication of the DVM is its extensive use of behavioral, as opposed to pathological, intervention strategies. While one must be trained to apply the model's components, not unlike motivational interviewing, for instance, licensure in psychology is not required. Improving participation rates in exercise behavior requires the communication of the results of behavioral assessments to the client. Behavioral assessment involves "the collection and analysis of information and data in order to identify and describe target behaviors, identify possible causes of the behaviors, select appropriate treatment strategies to modify the behaviors, and evaluate treatment outcomes" (Tkachuk, Leslie-Toogood, & Martin, 2003, p. 104). Behavioral assessment is well within the abilities of mental health professionals, behavioral medicine practitioners, and fitness coaches.

Creative new approaches to changing health behavior, including exercise, are needed. As Glasgow et al. (2004) have concluded, "If we are serious about evidence-based behavioral medicine and about closing the gap between research findings and application of these findings in applied settings, we cannot continue 'business as usual'" (p. 11). Nicassio, Meyerowitz, and Kerns (2004) and Prochaska et al. (2008) suggest the use of multiple specific methodologies for optimal intervention effectiveness. As Ockene (2001) correctly concludes, "change is a process, not a one-time event, and we can't expect people to make changes at a level for which they're not ready. Our interventions need to be directed to where the individual is" (p. 45).

More research is needed to understand the mechanisms through which interventions achieve efficacy. Researchers need to examine the antecedents and clinical issues that influence lifestyle change. Given the promising findings of the relatively scant available research on the DVM, future research on the DVM is warranted.

Integrative Diagnosis and Intervention: The High-Risk Model of Threat Perception Revisited

Roland A. Carlstedt

Emerging and converging evidence supports the perspective that the mind and body are inextricably linked and function in an integrative manner to mediate the manifestation of maladaptive autonomic nervous system (ANS) responses, which can result in symptoms and eventual illness. In addition, psychological profiles consisting of various traits and behavioral tendencies have been shown to play an important role in protecting individuals from disease and mental disorders. Identifiable mind-body processes and interactions can also be harnessed therapeutically to ameliorate symptoms and promote well-being (Moss, McGrady, Davies & Wickramasekera, 2003).

While this may be common knowledge, what has not been adequately explicated and disseminated to frontline clinicians are plausible integrative conceptual/explanatory frameworks that guide patient diagnostics and intervention beyond the cursory. For example, a practitioner could readily arrive at a diagnosis of panic disorder on the basis of self-report and subsequently initiate cognitive-behavioral therapy, or a psychiatrist could prescribe medication to treat depression. However, what is the probability that a specific patient will be amenable to cognitive-behavioral therapy or capable

of engaging, let alone benefiting, from it, or the odds that a depressive will comply with a prescription schedule and experience positive effects of a drug?

What can be done to obtain greater insight into key processes and behaviors that are crucial to the diagnostic and intervention process that are not apparent at face value, on the basis of self-report or clinical intuition? Could a practitioner, using a conceptually sound or relevant assessment battery or strategy at intake, be able to predict intervention amenability and compliance as well as mind-body response tendencies at baseline and in response to a treatment method? Moreover, to what extent could a patient's course of intervention be tracked, monitored, and analyzed in the context of real-world stimuli and stressors to establish the efficacy of a treatment modality? Importantly, what analytic methods can be used to determine statistically, at the level of the individual patient, longitudinal changes in mind-body responses, especially in ecological settings, for comparative purposes and the development of individualized databases of neuropsychophysiological functioning, symptom manifestation, cognitive and motor performance, well-being, and mind-body/mental health outcomes (intervention efficacy)?

Increasing levels (in terms of evidentiary value) of diagnosis, intervention, efficacy testing, and general analysis of mind-body functioning are necessary to adequately address critical clinical issues that can affect the evaluation and treatment process. Reaching diagnostic conclusions on the basis of patient self-report and clinical intuition without further testing and insight into what are often subliminal mind-body processes and cognitions that can affect the accuracy of a diagnosis, intervention selection, and efficacy is no longer tenable.

An integrative and conceptually based approach extends beyond initial impressions and practitioner assumptions to higher levels in the information, analytic, and evidence hierarchy. It involves the use of multifaceted assessment batteries and intervention procedures, efficacy testing, longitudinal monitoring, and data acquisition and storage methods for descriptive-exploratory-diagnostic, inferential-analytic, and clinical research purposes.

Central to such an all-encompassing integrative approach are models that enhance the accuracy of the clinical investigative/diagnostic process and potency/efficacy of interventions. Such models should have isolated predictor/independent and criterion/outcome variables and interactions among primary higher-order (PHO) individual difference factors that are intimately associated with or linked to key components or mediators in the health, mental health, and mortality equation, including external attending to stimuli (attention), physiological reactivity (ANS activation), and internal/subliminal cognitive processing/strategic planning/coping (subliminal attention).

One particular promising model, the high-risk model of threat perception (HRMTP) is explicated below (Wickramasekera, 1988). Conceptualized in the 1980s on the basis of independent lines of research in the realms of psychophysiology, health and personality psychology, behavioral medicine, and genetics, this model has generated over 100 peer-reviewed publications, but, as is frequently the case in the fields of mental health and behavioral medicine, sometimes the best models and research are not adequately disseminated across disciplines and end up languishing in the archives (Addis, 2002). However, since the HRMTP is integrative and highly credible in accounting for a host of clinical issues and phenomena relating to patient diagnosis and intervention, it should be revisited and seriously considered by researchers and practitioners alike. Clinicians who have used the HRMTP to guide practice have come to appreciate its diagnostic sensitivity and ability to predict intervention amenability and outcome (McGrady, Lynch, Nagel, & Zsembik, 1999). As such, it has be-

come a niche/insider research and practice model that should be receiving wider scrutiny and consideration by both researchers and practitioners.

BACKGROUND

The HRMTP (Wickramasekera, 1988) is a theoretical and applied model that attempts to assess and predict the risks of psychological and physical symptoms and illness posed by specific mind-body interactions. It has isolated a set of PHO risk factors (predictor variables) that have been shown to increase stress, drive physical symptoms, and influence intervention amenability, compliance, and efficacy. These factors are (1) hypnotic susceptibility (HS), (2) neuroticism (N), and (3) repressive coping (RC). In contrast to better-known guiding conceptual foundations that have made their way into clinical manuals and handbooks, including the stress-moderation, constitutional predisposition, illness-behavior models, along with independent/singular constructs such as type A personality, neuroticism, hardiness, and optimism, which tend to be unidimensional in their composition, the HRMTP advances multidimensional (integrative) driving hypotheses, predictions, research designs, and clinical procedures (see Hogan, Johnson, & Briggs, 1997, for an overview of the above cited competing models and constructs). The HRMTP emerged from a comprehensive review of competing insular models in health psychology and behavioral medicine. It led to the isolation of the above PHO individual difference factors as primary mediators in the health and mental health equation through the use of an integrative diagnostic and intervention framework.

In addition to its comprehensive system of patient evaluation, the HRMTP also advances an eclectic multifaceted approach to intervention consisting of psychophysiological psychotherapy, hypnosis, biofeedback, and cognitive-behavioral therapy (Wickramasekera, 1998). The application of these interventions is based on constellations of so-called risk factors that have been shown to predict intervention amenability. For example, a patient who is high in HS and N and low in RC would not be prescribed the same intervention as a patient exhibiting the opposite profile. The HRMTP approach does not assume that everyone will benefit from the same intervention and has demonstrated that a discriminating and individual differences-based approach to treatment is more effective than the application of interventions en masse.

A major goal of the HRMTP approach to intervention is to illuminate and document incongruence be-

tween verbal reports of distress and the actual underlying psychophysiology of patients during episodes of dysfunctional behavior, somatic complaints, and illness. The extent to which a patient's verbal report of pain or distress is consistent with actual medical tests and/or psychophysiological data frequently is consistent with or can be predicted on the basis of a patient's constellation of risk factors (see further on in this chapter). For example, somatizers and hypochondriacs, most of whom appear to be high in HS and N and low in RC, often report acute pain and distress that cannot be substantiated or validated on the basis of objective clinical tests. By contrast, many patients who are low in HS and N and high in RC tend not to report symptoms or psychological distress, yet tests reveal that they have medical disorders or psychological problems that they were not consciously aware of. Such mind-body incongruence is exposed by continuous monitoring of the physiology of patients during psychotherapy, or by comparisons of self-report with objective medical tests. Ultimately, psychophysiological and medical data is used to validate or refute a patient's self-report to arrive at a more accurate diagnosis and to intervene appropriately to alleviate symptoms and maladaptive behavior.

The ability to expose mind-body incongruence is central to the HRMTP intervention strategy, since there is a tendency on the part of practitioners to readily believe that "what you see is what you get" when it comes to patient body language, verbalizations, and self-report, despite documented inconsistencies between external behavior, behavioral cues, and actual internal (subliminal) psychophysiological reactivity (Fahrenberg & Myrtek, 1996; Wickramasekera, 1988). Inaccurate interpretations of patients' body language, verbalizations, and self-reports can lead to faulty diagnoses and clinical decisions as well as inappropriate applications of interventions. For example, because the fact that a patient exhibits supposedly normal body language does not necessarily mean that he or she is not experiencing underlying elevated sympathetic nervous system reactivity or hypertension. Overtly noticeable body language also can be a temporally isolated (post-facto) reaction to a preceding event, a response that is often fleeting and does not accurately reflect a patient's predominant ANS state. For example, patients who verbally express anger are not necessarily out of control psychologically. An inciting incident or animated response to therapist questioning does not necessarily warrant an immediate diagnosis of, say, anger management disorder. It is presumptuous to assume that body language, verbalizations, or self-report will reveal the same thing in all patients, as though a facial expression or verbal emoting

in one patient will reflect the same concomitant physiological responses in another one (Carlstedt, 2004). Consequently, according to the HRMTP, it is important to continuously monitor and analyze the physiology of patients during psychotherapy before attaching clinical meaning to patient body language, verbalizations, and self-report. Unfortunately, physiological monitoring of patients is rarely done, making it difficult to validate concurrently or criterion reference practitioner analyses of patients' behavior or self-reports. However, if one does not know the underlying physiology of a patient, it is speculative to assume congruence exists between the observable behavior and what a practitioner believes it to mean.

The HRMTP approach to interventions has shown that in addition to revealing mind-body incongruence, shifts in physiological reactivity that are elicited during psychotherapy reflect the perception of threat moving from unconscious to conscious memory, an event that is thought to occur when conflict is brought to consciousness (Wickramasekera, 1988, 1998). The concept of perception of threat is another central tenet of the HRMTP, with differential interactions of HS, N, and RC and their manifestations on health expected to be the greatest under conditions of high stress, when one's perceived well-being is threatened. Dramatic change in physiological reactivity in response to stimuli presented during psychotherapy is thought to reflect unconscious conflict or perception of threat reaching conscious awareness. Such an occurrence is associated with an increase in psychological distress but also frequently leads to an attenuation of maladaptive physiological reactivity, behavior, and symptoms (Wickramasekera, 1988). For example, a person being monitored during psychotherapy may exhibit a highly reactive physiological profile (e.g., high heart rate at baseline, excessive sweat activity) yet admit to no psychological distress and then suddenly, upon acknowledging previously repressed trauma or conflict, experience sudden reduced physiological reactivity. A person who finally reveals a previously unacknowledged emotion (e.g., being unhappy about a relationship) often exhibits an immediate reduction in baseline and chronically present levels of sympathetic nervous system (SNS) arousal and accompanying physical complaints (e.g., excessive muscle tension, fatigue) as suppressed feelings and thoughts come to consciousness. Immediately thereafter, the person may feel conscious psychological distress associated with a new awareness of an issue he or she did not want to confront but may nevertheless be pleasantly surprised when chronic symptoms attenuate (Wickramasekera, 1988). Once this occurs, patients are on their

way to achieving or restoring mind-body harmony, or homeostasis.

According to Wickramasekera (1998), these dynamic psychophysiological processes reflect “secrets that are kept from the mind, but not the body” (p. 81). In other words, you can try to fool yourself, but you cannot fool your body. The HRMTP predicts that specific interactions or constellations of risk factors (HS, N, and RC) are sufficient to account for somatic complaints, or positive physical findings.

CONCEPTUAL ORIGINS OF THE HRMTP

The conceptual origins of the HRMTP can be traced to a wide-ranging body of theory and research that has implicated chronic stress as a primary mediator of cardiovascular disease and cancer, which are today’s major causes of debilitation and death (Oeppen & Vaupel, 2002).¹ Whereas earlier in the century mortality was the greatest for infectious diseases, (e.g., the plague, polio, small pox) or what Wickramasekera (1988) refers to as “diseases of chance,” today behavioral and environmental factors are recognized as key mediators of morbidity and mortality. It has been estimated that about 80% of the visits to primary care physicians involve chronic diseases such as arthritis, asthma, diabetes, and cardiovascular disease, and that 50% of all deaths are attributable an unhealthy lifestyle or so-called diseases of choice (Wickramasekera, 1988). The landscape of illness today is marked more by chronic stress-related diseases, in which psychological factors and behavioral choices are central to prevention and treatment. Mounting evidence suggests that cognition and emotion interact to affect behavior and lifestyle choices that can exacerbate, alleviate, or prevent chronic medical disorders (e.g., House, Landis, & Umberson, 1988; Lepore, Mata, & Evans, 1993; O’Leary, 1990).

Wickramasekera (1988, 2003), in advancing the HRMTP, originally isolated nine factors that were hypothesized to increase the risk of stress-related physical symptoms and disease, including “subject variables,” which are thought to predispose an individual to illness; “situational variables,” or inciting “trigger” events

that often precipitate illness; and “buffers,” which play a protective role in preventing symptoms and illness. Subject variables include HS, N, and RC. These measures, depending upon their constellation and interactions (e.g., high HS, high N, and low RC), have been found to be potent predictors of symptom and illness onset, intervention amenability, and compliance and efficacy (Wickramasekera, 1988, 2003). Situational variables such as major life changes (e.g., loss of one’s job, a divorce) and multiple “hassles” that occur over a short period of time (e.g., family issues, conflict with one’s boss) are thought to increase the negative effects of select subject variable constellations. By contrast, protective buffers, including social support systems (e.g., positive interpersonal relationship; friends) and advanced coping skills for managing psychosocial stressors (e.g., proficiency in meditation), are predicted to attenuate the negative influence of constellations of subject variables and serve a protective role in staving off illness (Wickramasekera, 1988, 2003).

In order to help readers better understand how the above risk and protective factors interact to affect the course of symptoms and illness, an overview of the conceptual bases of these measures is presented.

SUBJECT VARIABLES

High HS

HS is considered a stable individual difference trait that may be partially genetically determined (Fromm & Nash, 2003). An individual’s level of HS is crucial to hypnosis, which can be defined as a psychophysiological state that is marked by an alteration of attention and reduction of cognitive awareness and critical-analytic thinking and leads to major distortions in perception, mood, and memory, as well as significant behavioral and biological changes (Wickramasekera, 1988).

Research suggests that HS is a mode of information processing occurring under various conditions but most often during states of high or low physiological arousal (Wickramasekera, 1988). HS can be viewed as an omnipresent and ongoing cognitive state independent of actually being hypnotized. About 10%–15% of the population can either readily access the hypnotic mode of information processing or are incapable of doing so, which also reflects the distribution of population extremes in this trait (high HS vs. low HS; ca. 10%–15%; Wickramasekera, 1988).

While people who are high in HS possess an increased ability to intensely focus on the task at hand,

1. Readers may notice that many of the following references date back decades. Nevertheless, such does not detract from their quality, since much of the cited research was of a seminal nature and still has an important place in the developmental history of various independent lines of research in behavioral medicine. This research also points to the fact that the HRMTP has been understudied in recent years for reasons that were elucidated in a general context in chapter 1.

in the context of health, high HS can lead to maladaptive cognitive responses, including the belief that minor physical sensations signal major illness. Such distorted attending is thought more likely to occur if an individual is concurrently high in the second subject variable, N. The interaction of high HS and high N is thought to lead to fixation on negative and catastrophic cognitions and associated visceral sensations and symptoms that occur in high neurotics, especially as a function of heightened stress. By contrast, people who are low in HS attend too little to physical sensations and physiological responses and are less attuned to emotions and cognitions that may precede or occur, concurrent to bodily reactions (Wickramasekera, 1988).

The neuropsychophysiological mechanisms of HS appear to have clinical implications; Wickramasekera (1983) found that 85% of a sample of 103 patients exhibiting somatic symptoms were either very high or low in HS. Three features of both high and low HS are thought to increase one's risk of developing psychophysiological (mind-body) disorders. First, the ability to hallucinate voluntarily and generate rich and vivid images of seeing, hearing, feeling, and smelling and engaging in fantasy activity up to 50% of waking time, which is common to HHS, are thought to have physiological consequences and likely to lead to somatic conditions. Wilson and Barber (1983), in a study of pregnant women, reported that 86% of those who had an illness or physical symptoms and directly related them to thoughts, fantasies, or memories were high in HS. In addition, 60% of the HHS group in this investigation reported false pregnancies and other false-positive signs, including fetal movements and morning sickness. By contrast, only 8% and 16% of comparison groups comprised of low- and medium-HS participants reported similar false-positive signs. Wickramasekera (1988), in interpreting these findings, posited that rich and convincing perceptual and cognitive experiences that are associated with HS, along with the neuropsychophysiological consequences of these experiences, provide a basis for the development of chronic symptoms. For example, while low-HS females who experience stomach discomfort in the morning are likely to attribute such a symptom to the fact that they have not eaten for hours, a high-HS female who is fixated on pregnancy is likely to think that she is actually pregnant.

A second feature contributing to risk in people who are high in HS is hypersensitivity to psychological and physiological change. Hypersensitivity is thought to be a learned process of symptom induction, whereby an individual who is high in HS exhibits a superior sensory memory or ability to transfer information from sensory

to short-term memory (Ingram, Saccuzzo, McNeil, & McDonald, 1979; Saccuzzo, Safnan, Anderson, & McNeil, 1982). Wickramasekera (1988) hypothesizes that people who are high in HS learn, remember, and consolidate the experience of acute symptoms and pain too well, thereby allowing it to become a chronic pain disorder. On the basis of this hypothesis, one could predict, for example, that patients with chronic or refractory back pain of a functional nature are likely to be high in HS.

Another possible learning mechanism of symptom induction may be the high-HS individual's hypersensitivity to sensory stimuli and a superior ability to discriminate between visceral sensations. For example, without analgesic suggestions, people who are high in HS are less tolerant of pain than people who are low in HS (Barabasz, 1983; Wickramasekera, 1988). People who are high in HS also have been found to have an unusual capacity for attention to and absorption in subjective events like pain and fear (Tellegen & Atkinson, 1974). This ability may be used to magnify their response to even minimal sensory and visceral stimuli (Wickramasekera, 1988). The above not only highlights maladaptive attending to pain and symptoms on the part of individuals who are high in HS, but their ability to attenuate pain and symptoms by using their enhanced focusing ability, provided that they are administered or engage in an intervention modality that is ideally suited to them (e.g., clinical hypnosis).

A third feature contributing to risk in people who are high in HS is their ability to voluntarily alter states of consciousness and memory functions (Evans, 1977; Kihlstrom, 1987). These abilities may be a protective reflex for dealing with biological hypersensitivity (Wickramasekera, 1988). For example, people who are high in HS can easily induce sleep at different times in diverse locations, can wake up at preselected times without an alarm, and are capable of learning during sleep without waking up. Retention for up to 6 months of simple information from such state-dependent learning has been demonstrated (Evans, 1977). It appears that maladaptive and/or aversive physiological responses can be learned in states of hyperarousal or hypoarousal (such as sleep). Wickramasekera (1988) proposes that negative-aversive expectations may alter the content of REM dreams and establish maladaptive patterns of muscular and vascular responses in sleep. Furthermore, people who are high in HS can readily learn fear and pain responses but are unaware of what was learned and where it was learned. Thus, the phenomena of incidental learning, source amnesia, or state-dependent learning that are associated with HHS may be the basis

of the strong resistance to extinction of over-learned and consolidated maladaptive responses associated with the development of somatic illness (Wickramasekera, 1988).

Low HS

People who are low in HS also display three features that put them at increased risk of developing somatic symptoms or illness: (1) a hyposensitivity to psychological and physiological changes, (2) a tendency to deny psychological causation of symptoms and feelings, and (3) delay in seeking medical investigation (Wickramasekera, 1988).

People who are low in HS are relatively insensitive to or deficient in attention to interrelationships between psychological (verbal-emotional) and physiological (proprioceptive-interoceptive) states (Wickramasekera, 1988). They tend to engage in a skeptical, critical, and analytic mode of information processing and tend to deny or attenuate minimal sensory cues from their bodies. They tend to lack or do not want to use verbal fantasy and imagination and prefer to think in specific and distinct terms. Low HS appears to be linked to alexithymia, a disorder that is characterized by an individual's lack of ability to use words to describe moods and emotions. It was first identified in people with psychosomatic disorders by Sifneos, Apfel-Savitz, and Frankel, (1977), who found that 73% of individuals who were classified as being low in HS were alexithymic, compared to only 8% of individuals who were high in HS. Alexithymics tend to attribute psychological changes to external physical changes and are likely to verbally inhibit or deny their feelings. When viewed in the context of trauma, their verbal inhibition has been associated with higher levels of physiological reactivity (Pennebaker, 1985). Consequently, for individuals who are low in HS, somatic symptoms may be the physiological manifestation of the verbal inhibition of trauma and psychosocial conflicts (Wickramasekera, 1988).

People who are low in HS may also be inhibited in resetting dysfunctional neurogenic (hypothalamic-pituitary-adrenal) feedback systems after stress incidents. That is, arousal levels or excessive sympathetic nervous system reactivity only slowly return to baseline states. Wickramasekera (1988) hypothesizes that the ability of high-HS individuals to enter states of altered consciousness (e.g., hypnosis) may facilitate the use of central nervous system processes like suggestion to reset dysfunctional peripheral (autonomic nervous system) feedback systems. For example, the neurogenic regulation of blood pressure through the resetting of baroreceptors, thereby restoring homeostasis after a

stress incident may involve such dynamics (Cannon, 1932). Individuals who are low in HS also appear to be more susceptible to psychosocial stress disorders because they are less aware of psychological stressors and deny the role of psychological factors in physical dysfunction (Wickramasekera, 1988).

Additional Findings

Barber (1984), in a review of investigations on the role of HS in altering internal physiological processes, came across various dramatic case studies that attest to such, including instances of warts, burns, and allergies being alleviated through hypnosis. For example, in a well-controlled study, Ikemi and Nakagawa (1962) reported that patients with a leaf allergy exhibited or suppressed dermatitis on the basis of hypnosis or suggestion alone. That is, patients, without knowing whether a leaf was caustic or harmless, exhibited allergic symptoms to leaves on the basis of suggestion alone. Findings from this study suggest that when individuals have been sensitized to skin contact by an allergen, their hypersensitive response to the allergen is reduced when they are not aware that they are in contact with the allergen (Barber, 1984). Barber concluded that an allergic response can be induced by the feeling, thought, or emotional belief that one is being stimulated by an allergen, even if one is not. This suggests that some immune responses, such as the T-cell-mediated skin response to an allergen, may be significantly influenced by what Barber refers to as "feelings-thoughts-imaginings-beliefs."

Although Barber's review primarily presents dramatic instances of hypnotically mediated symptom attenuation in non-life-threatening afflictions, hypnosis and HS have also been shown to affect the course of major diseases. For example, Greenleaf, Fisher Miskowski, and DuHamel (1992) reported that coronary bypass patients who were in the medium range on HS stabilized more rapidly in the intensive care unit than those who were high or low in HS. Consistent with Wickramasekera's (1988) predictions, high or low HS was found to be a significant predictor of recovery in the ICU, independent of the experimental application of hypnosis to patients in this investigation.

HS has also been studied in the context of phobic behavior. John, Hollander, and Perry (1983) reported 55% of a sample of women who were phobic to snakes, spiders, or rats to be high in HS. Gerschman, Burrows, Reade, and Foenander (1979) also found 48% of a dental phobia sample to be high in HS. Both studies suggest that high HS may predispose an individual to an inability to cope with stress associated with phobic disorders.

HS has also been used to differentiate serious psychological disorders, including hysterical psychosis and schizophrenia. Spiegel and Fink (1979) found individuals who were diagnosed with hysterical psychosis to be mostly high in HS. Trance states, rapid and florid psychotic decompensation, delusions, ideas of reference, loose associations, and affect states ranging from indifference to intense agitation observed during hysterical psychotic episodes have been associated with high HS (Spiegel & Fink, 1979). By contrast, schizophrenics tend to exhibit little or no HS, since disorders of thought or mood seem to interfere with the intense concentration that characterizes HS (Spiegel & Fink, 1979). The authors of the study proposed that the measures of HS that tap the capacity for attentive, intense focal concentration with diminished peripheral awareness that occurs with the hypnotic state could be used to discriminate between psychosis of hysterical origin and schizophrenia and other malignant psychiatric disorders.

NEUROTICISM

The second risk factor for developing somatic illness or symptoms in the HRMTP triad is neuroticism. A high level of N is associated with the tendency to recognize and recall predominantly aversive memories (Wickramasekera, 1988). N is considered to be a longitudinally stable trait independent of objective stress. In clinical samples there is frequently large incongruence between self-reports of distress and direct psychophysiological measures of stress (Wickramasekera, 1988). High neuroticism is associated with lability of the ANS and hyperreactivity of the SNS and appears to have a genetic origin (Eysenck, 1960; Shields, 1962). Self-reported N has been linked to the limbic system by Eysenck (1983) and is manifested psychophysiological as elevated baseline levels of muscle tension, skin conductance, heart rate, and blood pressure, and delays in returning to baseline after episodes of stress (Eysenck, 1983). High N appears to be an unjustified and exaggerated amplification of physical concerns and manifestation of functional symptoms, as opposed to a sign of physical disease per se (Geen, 1997; Wickramasekera, 1988).

The tendency to exhibit a consistently elevated ANS response profile appears to have clinical implications. For example, people showing maximum physiological reactivity in the cardiovascular system may be at high risk of developing myocardial infarction or stroke (Krantz & Manuck, 1984), whereas those who exhibit hyperreactive responses in specific muscles may be at greatest risk for chronic back pain or tension headache conditions (Flor, Turk, & Birmbaumer, 1985; Philips,

1977). Wickramasekera (1988) views the most physiological reactive system as an individual's "window of maximum vulnerability" for developing clinical symptoms when under stress (p. 17).

High N frequently leads to catastrophizing. In earlier conceptualizations of the HRMTP, catastrophizing was presented in its own right as an independent risk factor (Wickramasekera, 1988). However, more recently, catastrophizing, which is marked by a tendency to expect the worst to happen when one thinks about the future, has been viewed more as a consequence of interactions between HHS and high N (Wickramasekera, 1994). Catastrophizing can involve becoming frequently and intensely absorbed in negative psychological or sensory events and exaggerating aversive properties of such events with negative self-talk or auto-suggestion. Catastrophizing has at least two response components. Attentional focus is on, first, the sensory or visceral events that are associated with symptoms and, second, remembering or anticipating a wide variety of negative physical and psychosocial consequences and antecedents of the aversive or symptomatic event (Wickramasekera, 1988). It has been hypothesized that many internal and external cues that trigger catastrophizing are outside conscious awareness (Dixon, 1981). Numerous studies have linked catastrophizing to somatic complaints. For example, Chaves and Brown (1978) found that the majority of chronic pain patients are catastrophizers and have higher pain ratings than so-called copers. In addition, 86% of catastrophizers requested antianxiety or antidepressant medication to deal with psychological stress associated with their pain, compared to only 12% of copers (Chaves & Brown, 1978). Wickramasekera (1988) proposed that the predisposition to spontaneous panic attacks that is central to the formation of phobias is mediated by catastrophizing cognitions that subjectively reduce pain tolerance, spiral anxiety, and generate self-reports of hopelessness. Moreover, it appears that chronic pain, panic, fear disorders, and depression may have common biological bases involving serotonin and norepinephrine metabolism (Sternbach, Janowsky, Huey, & Segal, 1976).

REPRESSIVE COPING

RC is the third risk factor in the HRMTP triad. It is characterized by implicit (unconscious) defensiveness and the tendency to inhibit affect. The Marlowe-Crown Scale is frequently used to measure this capacity for blocking negative perceptions, memories, and moods from consciousness, a style of coping that appears to promote inattention to aversive situations and the amplification

of positive situations (Crowne & Marlowe, 1960; Wickramasekera, 1988). Individuals who are high in RC frequently exhibit incongruence between subjective positive self-report and physiological and behavioral indicators of distress and tend to have a poor memory for negative emotional experiences (Lane, Merikangas, Schwartz, Huang, & Pushoff, 1990; Weinberger, Schwartz, & Davidson, 1979; Wickramasekera, Davies, & Davies, 1996). The self-deception associated with RC appears to make individuals who are high in this trait susceptible to developing somatic and/or behavioral symptoms (Lane et al., 1990). By contrast, people who are low in RC are considered less adept at self-deception and appear more likely to experience psychological symptoms such as depression and anxiety but are less likely to experience psychophysiological symptoms (Lane et al., 1990; Wickramasekera, 1998).

RC has also been viewed as a “self-enhancing cognitive style” that promotes the rapid dampening of negative affective responses to stressors, maintenance or enhancement of self-esteem, and a lowered risk for psychopathology (Tomarken & Davidson, 1994, p. 339). Neurophysiological studies of RC have led some researchers to characterize RC as a “functional disconnection syndrome” between the left hemisphere and other cortical or subcortical regions that mediate autonomic and neuroendocrine components of affective responsivity (Davidson, 1984; Schwartz, 1990). For example, Davidson (1984) demonstrated relative deficits in interhemispheric transfer of negative affect from the right to the left hemisphere. This deficit in cross-callosal transfer of aversive information is thought to account for reduced psychopathology in people who are high in RC (Tomarken & Davidson, 1994). The heightened ANS and endocrine activation that is frequently exhibited by individuals who are high in RC is thought to reflect the mobilization of processes that inhibit distress, facilitate goal-oriented behavior, or both (Tomarken & Davidson, 1994). Repressive and defensive coping styles have also been associated with impaired immune function and increased risk and worsened prognosis in neoplastic diseases. In their opioid-peptide hypothesis of repression, Jamner, Schwartz, and Leigh (1988) propose that RC is associated with increases in the level of endorphin in the brain and can lead to diminished immunocompetence and hyperglycemia. In support of their hypothesis, they found that repressive and highly anxious patients demonstrated significantly decreased monocyte counts and elevated eosinophile and serum glucose levels and increased self-report of reactions to medications.

Specific to the HRMTP, mechanisms of RC are hypothesized to block the perception of threat from consciousness; RC is considered a psychological mechanism

that can increase the incongruence between subjective perception (consciousness of threat) and physiological or behavioral markers of threat perception (Wickramasekera et al., 1996). High RC has been associated with various health problems, including coronary heart disease and hypertension. In a case study, Mann and Delon (1995) reported on the effects of RC on blood pressure in a 49-year-old female who had been treated unsuccessfully for 6 years for severe and refractory hypertension. Although this patient did not acknowledge any extraordinary stress or distress in her life, she did disclose having been raped in the past (3 decades ago). Surprisingly, her revelation of a previously repressed traumatic event led to a dramatic and sustained improvement in her blood pressure.

In another case study, Wickramasekera et al. (1996) reported on a female patient with severe food and respiratory allergies. Over the course of 15 years this individual had been unsuccessfully treated for a variety of symptoms stemming from her allergies. Upon evaluation, it was discovered that the patient had two risk factors for covert somatization, including high RC. A psychophysiological assessment revealed the strongest SNS reactivity or activation in skin conductance and peripheral temperature. This patient’s mind-body dysfunction was reflected in her cold and wet hands and multiple chronic somatic symptoms. Although the patient reported no psychological distress, psychotherapy later revealed that she had felt psychologically dominated (abused) by her husband for years. After she admitted these repressed feelings, her symptoms attenuated. Her food and respiratory allergies cleared up and her psychophysiological profile (i.e., hyperreactivity in skin conductance and peripheral temperature) showed significant improvement at 7-month follow-up.

Other research has revealed that individuals classified as repressors, inhibitors, or suppressors had higher cancer rates more elevated blood pressure levels and higher frequency of physical diseases in general than more expressive individuals (Pennebaker, Hughes, & O’Heeron, 1987). In addition, Derogatis, Abeloff, and Melisaratos (1979) found that women who lived the longest after the diagnosis of breast cancer were those who were most openly angry and depressed. Thus, not disclosing thoughts and feelings over time appears to be correlated with disease and mortality.

MAJOR LIFE CHANGES AND HASSLES (TRIGGERS)

It should be noted that HRMTP subject variables are hypothesized to primarily exert their influence as

risk factors in the context of the perception of threat of both objective and subjectively perceived and subliminal stressors. Objective stressors such as major life changes like a divorce, change of job, death of a friend, or even the birth of a child can be major sources of psychosocial stress and precipitators of somatic illness since they challenge an individual's ability to adjust to change (Holmes & Rahe, 1967). Subjectively perceived and subliminal stressors involve personal fears, internal feelings of anger, and feelings that one is being threatened, along with catastrophizing cognitions in the absence of any overt, external, or real objective inciting stimuli (Wickramasekera, 1988).

Major psychosocial stressors appear to activate the ANS-SNS fight-or-flight response (Selye, 1956). Mason's (1971) research suggests that physical and psychosocial stressors operate through a common psychological mechanism: the perception of threat to an individual's well-being. Conversely, in the absence of a perception of threat to well-being, changes in autonomic (SNS) responses may not occur despite the presence of physical stressors. Since the perception of threat is a learned response, it can occur chronically in reaction to conditioned stimuli such as cognitions and images in the total absence of any unconditioned response, such as symptoms (Wickramasekera, 1988).

Three components of psychosocial stressors are thought to interact with HRMTP subject variables in people who are at high risk of developing somatic disorder and disease: ambivalence, ambiguity, and chronicity. Ambivalence to psychosocial stressors elicits both approach and avoidance tendencies, either sequentially or simultaneously. For example, changing a job after many years can be a relief but also lead to regret, with the sources of psychosocial stress often being ambiguous and difficult to perceive and define. Subtle pressure from a boss to perform may not be recognized as an on-the-job source of chronic stress, yet were one to monitor the physiology of a vulnerable individual (elevated HRMTP subject variable risk factors) in such a situation, one would very likely discover chronic elevated SNS activation. Psychosocial stressors tend also to be episodic, chronic, and resistant to rapid extinction through ANS fight-or-flight responses (massive SNS activation). For example, one cannot rid oneself of an unruly child by physically attacking him or her (Wickramasekera, 1988).

An accumulation of major life changes appears to be associated with greater morbidity or a higher probability of illness. For example, Holmes and Rahe (as cited in Lerner, 1996) measured life change units to quantify the probability that a person would become ill. The death of a spouse was valued at 100 points, whereas

trouble with a supervisor counted as 23 points. Subsequent prospective studies showed that 80% of individuals who had a score of more than 300 points developed a serious illness within 2 years, compared with only 30% of those with a score of less than 150 points.

Daily Hassles

Hassles are considered ongoing stresses and strains in everyday life. They are also referred to as micro-stressors or chronic role strains (Wickramasekera, 1988). Getting stuck in traffic, running out of gas, and losing one's keys are examples of daily hassles. The massing of daily hassles is thought to be strongly related to the development of somatic symptoms, with resultant health problems remaining long after the effects of major life events were statistically accounted for (Wickramasekera, 1988). Individuals who have experienced major life changes in the last 6 months tend to be concurrently exposed to numerous minor hassles that increase the already elevated probability that somatic symptoms (e.g., headaches, chest pain, stomach problems) will be manifested (Wickramasekera, 1988). Brantley and Jones (1993), in a review of the literature, found that minor daily stress (i.e., hassles) potentiated symptoms associated with numerous illnesses, including the emotional arousal and bronchial spasm associated with asthma. Stressors were also implicated in the onset and exacerbation of diabetes mellitus, in that they disrupt glucose metabolism, and compliance with health-facilitating behaviors (e.g., diet adherence, monitoring insulin). Mental stress has also been shown to be a potent mediator of the vasoconstriction that is associated with myocardial ischemia (Krantz, Gabbay, Hedges, Leach, Gottdiener, & Rozanski, 1993).

The psychophysiological mechanisms associated with daily hassles resemble those that are activated during major life changes. SNS fight-or-flight responses are activated in the presence of the perception of threat. Chronic exposure to daily hassles is thought to have an additive effect in potentiating symptoms and illness, especially in the presence of one or more HRMTP subject risk factors and the absence of coping skills for reducing stress (Wickramasekera, 1988).

SOCIAL SUPPORT SYSTEMS AND COPING SKILLS (BUFFERS)

Caplan (1974) defines social support as the comfort, material help, and information one receives through

formal or informal enduring contact with individuals or groups. Social support systems are essential psychological buffers that an individual can rely on and utilize to reduce the effects of stressors. Social support systems appear to assist individuals by (1) removing or altering a threat, (2) changing the meaning of a threat, and (3) changing an individual's emotional reaction to a threat (Wickramasekera, 1988).

Social support systems have been clearly linked to recovery, rehabilitation, adaptation to illness, and mortality. A review by Cohen (1985) revealed that people with supportive spouses, friends, and family members were in better health than those individuals who lack positive social contacts. House, Landis, and Umberson (1988), in a review of prospective studies, also found that more socially isolated and less socially integrated individuals were less psychologically and physically healthy and more likely to experience premature death. Beman and Syme analyzed mortality probability in a sample of 4,775 adults between the ages of 30–69 (as cited in House et al., 1988). They assessed various kinds of social ties, including marriage, contacts with extended family and friends, church membership, and other formal and informal affiliations, and found that each type of social relationship predicted mortality through the subsequent 9 years. A combined “social network” index was found to be a significant predictor of mortality, with individuals who were lowest on the index having twice the rate of mortality of individuals who were highest on the index even after health status, socioeconomic status, smoking, alcohol consumption, physical activity, obesity, race, life satisfaction, and preventive behaviors were controlled for. In addition, Orth-Gomer, in analyzing mortality in a random sample of 17,433 Swedish adults ages 29–74, found that the greatest increase in mortality occurred in the most socially isolated third of this cohort (as cited in House et al., 1988).

The mechanisms underlying the negative consequences of a lack of social support systems are thought to be psychophysiological in nature. For example, Casse found that the presence of a familiar member of the same species buffered the impact of experimentally induced stress by reducing the secretion of free fatty acids, a compound implicated in various disorders, including hypertension (as cited in House et al., 1988). Other clinical and laboratory data also suggest that the presence of or physical contact with another person can modulate human cardiovascular reactivity in general (Lynch, as cited in House et al., 1988). Moreover, being petted by humans, or even their mere presence, has been shown to reduce cardiac responses to stressful

situations in dogs, cats, horses, and rabbits (Lynch, as cited in House et al., 1988).

Bovard formulated a psychophysiological theory to account for the facilitative effects that social relationships and interpersonal contacts can have on health (as cited in House et al., 1988). In reviewing a wide range of human and animal studies, he suggested that social relationships and contacts, mediated through the amygdala, activate the anterior hypothalamic zone, which stimulates the release of human growth hormone, thereby inhibiting the posterior hypothalamic zone-mediated secretion of adrenocorticotrophic and cortisol catecholamines (stress hormones) and associated SNS hyperactivity. These mechanisms are consistent with the impact of social relationships on mortality from a wide range of causes and with the findings of studies on the adverse effects of lack of social relationships on the development of human and animal infants (Bowlby, as cited in House et al., 1988).

The ability to handle psychological stress or chronic difficult psychosocial relationships that elicit the fight-or-flight response has been linked to coping skills. At least three kinds of coping skills have been identified: (1) problem-focused coping involves taking direct action on the environment or oneself to remove or alter the threat, (2) emotion-focused coping involves actions or thoughts to control negative feelings that result from a threat, and (3) perception-focused coping consists of cognitive attempts to attenuate or alter the importance of the threat (Wickramasekera, 1988).

Coping skills appear to be a major factor in the reduction of excessive and ongoing SNS reactivity (Wickramasekera, 1988). Rosenbaum (1980) conceptualized coping skills as involving four components of learned resourcefulness: (1) the use of cognitive and self-instructions to cope with emotional and physiological responses; (2) the application of problem-solving strategies, including planning, problem definition, evaluation of alternatives, and anticipation of consequences; (3) the ability to delay immediate gratification; and (4) the general belief in one's ability to self-regulate internal events.

The benefits of positive coping skills have been reported in numerous studies. For example, Ornish et al. (1990) reported that patients with coronary heart disease who were motivated to make comprehensive lifestyle changes, including going on a vegetarian diet, moderately exercising, and eliminating smoking, experienced a regression of atherosclerosis. Another coping strategy, religious beliefs, has been extensively studied, with consistently strong correlations reported between participation in religious activities, behaviors

and thoughts, and positive physical health and ANS responding (Rowan, 1996).

High amounts of social support and satisfaction with such support along with good coping skills appear to mitigate the relationship between stress and concurrent manifestations of symptoms. By contrast, high or low HS and high N strengthen the relationship between stress and symptoms. In addition, the onset of major life changes or minor hassles (micro-stressors) within a concentrated period of time is thought to precipitate the onset and severity of mental and/or physical symptoms (Wickramasekera, 1988).

ORIGINAL PREDICTIONS FROM THE HRMTP

Although the isolated HRMTP PHO subject variables (risk factors) may, independently, be weak predictors of symptom onset, morbidity, and clinical outcome, they have been shown to interact to mediate complex neuropsychophysiological responses in the presence of overt and covert stressors and perceived threat to well-being. Individuals at greatest risk of developing symptoms and illness are those who have elevated levels of predisposing PHO factors and a lack of support systems and coping skills and who have experienced massive multiple major life changes and/or hassles. Individuals who are at lowest risk are those who have none of the predisposing PHO risk factors and have multiple effective support systems and coping skills (Wickramasekera, 1988).

In addition to the above global synopsis, the HRMTP makes the following specific predictions:

- (1) The development of somatic symptoms and illness is *always* a function of multidimensional interactions among psychological risk factors and genetics. This prediction can be considered the PHO tenet of the HRMTP, according to which specific constellations of HRMTP identified risk factors are potent enough to mediate differential neuropsychophysiological responses to stress, and these factors have primacy or higher order functional and mediating dominance over all other psychological factors in affecting ANS reactivity. Isolated HRMTP subject variables are expected to strongly influence symptoms, morbidity, and clinical outcome.
- (2) Neuroticism and the state of negative affect are essential to but not sufficient for the development of psychosomatic symptoms and illness. This implies that neuroticism and negative affect play central roles in the etiology of symptoms and illness and can be referred to as the “great mediators” of maladaptive neuropsychophysiological responses to stress. However, maladaptive manifestations of N are most likely to occur in the context of the perception of threat that is posed by a real or perceived stress or, when an individual is concurrently high in HS.
- (3) Individuals who are high in HS and low in RC are more likely to develop both psychological and somatic symptoms. By contrast, those who are low in HS and high in RC will develop primarily somatic symptoms. Individuals who are high in HS and low in RC can be expected to consciously experience psychological distress and the perception of threat during periods of heightened stress. This dynamic is strengthened in the presence of high N and the associated negative and catastrophizing cognitions that people who are concurrently high in HS tend to intensely focus on. The result of unmitigated attending to negative thoughts and subsequent generation of symptoms that frequently occur with high N can be chronic vasoconstriction and consequent inability to relax or return to a baseline state of homeostasis. By contrast, individuals who are low in HS and high in RC are less likely to experience psychological distress or perceive stress, especially if they are low in N. RC, which in earlier conceptualizations of the HRMTP (Wickramasekera, 1988) was referred to as covert neuroticism, is associated with higher states of SNS activation at baseline, a dynamic that is found in people who are high in RC. Psychological imperviousness or unawareness of psychological factors and influences in life can serve to protect an individual from mental distress or stress, but with a tradeoff, namely, chronic hyperphysiological reactivity.
- (4) Individuals who are high in HS and experiencing somatic symptoms are more likely to seek help for their problem in a mental health setting than in a medical setting, since they are more likely to recognize the influence of mind-body interactions in the disease process. Such behavior would be consistent with the known dynamics of high-HS patients, who are more attuned to psychological influences and are more cognizant of stress and distress that may lead to symptoms, especially as a function of high N. Going to a psychotherapist instead of a physician can have health consequences if a mental health provider is not trained to recognize and assess psychophysiological symptoms/disorders in the context of behavioral medicine/medical diagnostic

and intervention procedures (see chapters 1 and 31). Knowledge of HRMTP PHO factors can be crucial to treating a patient appropriately on the basis of mind-body response tendencies that are endemic to a specific constellation (e.g., HHS and HN).

- (5) The majority of patients in primary medical care settings are low in HS and high in RC and are more likely to avoid referral to mental health settings. By contrast, patients who are low in hypnotic susceptibility are less likely to seek assistance from mental health practitioners/psychotherapists. Low HS is associated with a skeptical cognitive style and unawareness or denial of mind-body influences/effects on symptoms and health. This skeptical cognitive style is compounded by high RC. These patients can benefit from intervention modalities that provide objective information about psychophysiological processes (e.g., biofeedback). However, because patients who are low in HS and high in RC can be difficult to motivate to engage in interventions, especially psychological ones, the HRMTP advocates a so-called Trojan horse approach for the purpose of covertly and subtly introducing potentially beneficial treatment procedures (Wickramasekera, 1988).

These predictions have much anecdotal support and serve a valuable clinical utility. They should be further tested in the context of a large research trial, including the universal clinical trial (see chapter 31). HRMTP PHO factors, depending on their constellation, are potent predictors of cognitive style, perception of stress, and ANS response tendencies to stress, as well as intervention amenability and compliance. They provide valuable clues and insight into subliminal mind-body processes that are not readily apparent or discernable solely through body/facial language, self-report, or clinical intuition or gleaned from medical or psychological tests that do not tap the unconscious dynamics and behavioral tendencies that have been associated with these measures (Wickramasekera, 1988).

ADDITIONAL PREDICTIONS: EXTENDING THE HRMTP

In addition to the above hypothesized relationships between PHO subject variables and symptoms, intervention, and treatment choices (medical vs. mental health domain), the following predictions are made on the basis of known dynamics of HRMTP PHO isolated individual differences measures.

Delays in Diagnosis and Treatment Onset

Individuals with symptoms seek help differentially. Not everyone who feels ill or experiences pain or psychological distress goes to the emergency room, makes an appointment with a physician, or contacts a psychotherapist. In the extreme, hypochondriacs may arrange to be evaluated daily, whereas other people rarely admit to being sick or experiencing pain (even in the presence of objective evidence) and therefore never schedule a consultation with a doctor or psychologist.

This latter type of individual is expected to face a greater risk of experiencing an acute medical incident or developing a chronic disorder that becomes a threatening disease. The ability to discern and predict which person is likely to undergo regular physical examinations or respond appropriately upon pain or symptom onset by seeking out a physician and who does not can have important consequences for patients, physicians, and the broader health care system. For one, symptoms that are addressed and treated early usually increase the probability that a disorder can be eradicated. In best-case scenarios some illnesses and disorders can be averted on the basis of preemptive medical responding. Identifying those individuals who are more likely to deny symptoms, in addition to being potentially life saving, also has practical and financial implications, since illnesses that can be staved off or ameliorated in their early stages are usually less costly for all entities in the disease and health care equation, including patients themselves, hospitals, insurance companies, and an affected person's family and micro-economy.

Based on the characteristics of HRMTP PHO subject variables (individual difference risk factors), it may be possible to screen individuals for what can be referred to as diagnostic aversion (DA) or clinical denial (CD) behaviors. The extent of DA/CD is hypothesized to vary as a function of level of HS and RC, with high RC being the primary mediator of denial of symptoms, pain, and psychological discomfort and the consequent failure to seek medical or psychological assistance. Low HS is expected to reinforce the tendency of high RC toward denial and feelings of imperviousness or indestructibility through the suppression of cognitive mechanisms that facilitate openness or recognition of feelings and sensations that are associated with symptoms that should not be ignored. While low HS can be involved in the DA/CD process, high RC is of primary importance, especially since this PHO subject variable has also been associated with heightened pain tolerance and the tendency to rationalize away or dismiss the existence of what would normally be considered objective potential

threats to one's well-being (e.g., chest pain or a noticeable lump) that warrant further investigation (Wickramasekera, 1988).

Coronary Artery Disease: Unexpected Myocardial Infarction and Sudden Death

In the realm of cardiology and emergency medicine, physicians frequently encounter patients with no prior history of coronary artery disease who suddenly experience a debilitating cardiac incident that requires immediate treatment and hospitalization. Others with no known or reported symptoms suddenly succumb to a myocardial infarction. Although asymptomatic heart disease is thought to exist, it is here hypothesized that such is rare, if even possible, and that a lack of known or reported symptoms (either to a physician or other people in a person's life) does not preclude the existence of overt and dramatic as well as subtle symptoms indicative of a cardiovascular problem, including coronary artery disease (CAD), often for years or decades prior to a final catastrophic cardiac event. In other words, people who experience a sudden major heart attack that requires involuntary hospitalization or leads to death, in the absence of known or reported symptoms or underlying heart disease (usually because they have avoided examination) actually do have symptoms. However, they may remain subclinical in that they recede or attenuate and do not lead to collapse and involuntary hospitalization (this type of individual will not voluntarily seek out a physician). It is further hypothesized that individuals who are most likely to be perpetual or chronic DA/CD are those who are high in RC or low in HS and high in RC. As previously mentioned, high RC is associated with the tendency to deny threats to one's well-being, greater pain tolerance, heightened self-esteem, and imperviousness to psychological stress. An individual who is high in RC is likely to deny symptoms to the extent of not feeling pain or distress so long as he or she doesn't fall over or drop dead. While psychological repression and feelings of control and invulnerability are associated with perceived mental well-being, high RC comes with a price, namely, chronic ANS-SNS hyperreactivity and concomitant vasoconstriction, which may contribute to hypertension, underlying atherosclerosis, and eventual death, all in the supposed absence of symptoms—absent, in the conventional sense of not having been reported, or even felt, but nevertheless present, subliminally, as reflected in underlying, slowly developing pathology that may first be discovered at autopsy.

The consequences of failure to preemptively identify vulnerable individuals, who, ironically, may actually perceive themselves as being invulnerable, can be dire. While these hypotheses still need to be tested, and because little research has addressed intervention amenability, compliance, DA, CD, and psychological mediators in sudden cardiac death syndrome, it is recommended that PHO subject variable components of the HRMTP be investigated in the context of these clinical phenomena.

Cancer and Other Slow-Developing Diseases

The aforementioned dynamics, hypotheses, and predictions likely apply to cancer as well and most medical conditions that have a longitudinal course of progression from symptom onset until involuntary hospitalization can no longer be avoided. Whether it's the woman who ignores or rationalizes away a lump in her breast or a man who denies feeling any pain in the leg despite having bone cancer, the psychological defense mechanisms that foster feelings of control and mental well-being in the moment can be insidious and lead to an individual's apparently sudden demise.²

HIGH REPRESSIVE COPING: PHOBIA OR PSYCHOLOGICAL ARMOR?

It should be noted that while certain behavioral characteristics of high RC are consistent with phobic behavior, including a strong aversion to, for example, seeing a doctor or dentist, RC is recognized as a distinct psychological and behavioral PHO subject variable both in the context of the HRMTP and in general life contexts. What most distinguishes it from phobias is that RC is a subliminal process. Individuals who are high in RC tend not to be aware of subliminal psychological processes that mediate the cognitions and behavior that they engage in. They are not introspective regarding their behavior. People who are high in RC are unconsciously motivated to maintain the status quo and mental well-being. By contrast, phobic individuals know that they

2. The author of this chapter is seeking to implement clinical trials relative to the above hypotheses and predictions and encourages interested researchers and research groups from the fields of cardiology, oncology, emergency medicine, and other relevant specialties to contact him regarding the funding and implementation of such a project.

fear something; they are aware of their weaknesses and neurotic irrational behavior and seek out treatment (Antony, Brown, & Barlow, 1997).

INTERVENTION AMENABILITY AND COMPLIANCE

The propensity toward diagnostic aversion and clinical denial in individuals who are high in RC (or low in HS and high in RC) increases the probability that such people are more likely to not be amenable to most interventions and therefore apt to be noncompliant should an intervention be forced upon them (following discharge from the hospital) due to an acute medical event that requires hospitalization. Behavioral tendencies associated with RC can function as major confounds in clinical and research contexts. For example, a patient who is high in RC, when hospitalized, may have no choice but to take medication that is administered with oversight and experience symptom amelioration and eventually be released. Thereafter, doctors might assume that such a patient will comply with a drug schedule that was prescribed at the time of discharge. However, if they do not screen for PHO subject variables and have no knowledge of behaviors (intervention compliance) that are associated with RC, physicians may be surprised days or weeks later when the same patient is readmitted (which usually is a serious matter since the high-RC patient is not likely to voluntarily admit him- or herself to a hospital). Such a scenario may perplex attending physicians, who have no explanation for why a drug that usually works did not in this and other patients (up to 33% of the population) who are unknowingly high in RC or low in HS and high in RC. While noncompliance or faulty compliance may be assumed in such instances, it is doubtful that patients who are high in RC would admit to not following treatment orders, since doing so would signal mental weakness and be at odds with the heightened self-perceived sense of psychological control and high self-esteem that characterize this PHO measure.

PHARMACOLOGICAL INTERVENTION: MEDICAL AND PSYCHOTROPIC CONTEXTS

Cognizance of patients' constellation of HRMTP PHO subject variables should be a priority in medical and pharmacological contexts to help better account for

cases of noncompliance and resultant outcomes that are inconsistent with what one would expect on the basis of a drug's known effects. While dealing with the aversion to seeking a diagnosis and treatment and noncompliance behaviors that are endemic to high RC may be easier said than done, Wickramasekera (1988) developed a novel approach for treating patients who are predisposed to noncompliance and failure to engage in interventions. His Trojan horse method is a circuitous technique that uses diversionary tactics to motivate a patient to focus on objective physiological signals that emanate from biofeedback instruments to convince skeptical low-HS and high-RC individuals that they can control mind-body responses.

Relative to drug trials, high RC can act as a confounding or extraneous variable that can unknowingly skew group samples. Since it is assumed that all traits and behaviors are normally distributed in the global population, one could expect that about 33% of potential study participants will be high in RC. However, because of the very nature of RC, it is doubtful that individuals who are high in this PHO measure will ever volunteer to participate in a drug trial or, if hospitalized and automatically enrolled in a drug trial, would comply on follow-up after being released. Consequently, both classically structured clinical drug trials that rely on random selection for obtaining participants and emergency room- and hospital-based investigations may be susceptible to PHO factor artifact. This can change outcome or lessen the predictive potency of a study's independent variables. In other words, the effect of a drug on a symptom or the overall ability to ameliorate symptom clusters or eradicate a disease or disorder could be statistically compromised, when, in fact, had one controlled for RC, the predicted efficacy of a drug might have been supported. This possibility points to the need to consider and control for the HRMTP PHO isolated individual difference variables in drug investigations as a matter of routine.

DUAL PLACEBO-NOCEBO EFFECTS: PRACTITIONER-PATIENT DYNAMICS

The success of psychotherapy and other interventions that are designed to ameliorate symptoms and conditions that have mental or psychological components is predicated, at minimum, on the belief that they work. The belief that a treatment works may be more important than objective evidence that substantiates notions of intervention efficacy, especially in more nebulous areas like psychotherapy, although the placebo effect is

well established in medical circles. While beliefs may be important, especially in the immediate context of an actual psychotherapy session and perhaps shortly thereafter and then again prior to the next scheduled session, they may in the long run hinder more substantive and real measures of outcome success. For example, a patient with depression may week after week see a psychotherapist who is convinced that existential issues are at the heart of his or her client's somber affect, hopelessness, and gloomy outcome. In the course of therapy, as early as the intake and initiation of an existential psychotherapeutic intervention, the patient may become convinced that his or her therapist is not only right but caring and will succeed in bringing joy back into his or her life. In this scenario both the patient and practitioner are on the same page; they see eye to eye and are committed to a clinical goal through the use of an insight-based approach and treatment strategy and technique.

But is the patient really getting better, or does he or she merely "feel" better just before, during, and for a short period after therapy, only to relapse two days later before feeling good again, knowing the next session is just around the corner? And is such a rhythm conducive to averting the potential medical consequences that are associated with chronic depression, even with the occasional escape from its most debilitating symptoms? Are the therapist and patient even aware of these potential medical consequences, or is the therapeutic goal just a matter of feeling better for longer stretches of time than previously?

What this is meant to illustrate is that a mutual belief system may be at the heart of many therapeutic alliances and, although well intentioned, may result in little more than a therapist-patient-mediated dual placebo effect that in the end leads to temporally isolated bursts of symptom amelioration that make the patient feel good but do little to alter maladaptive ANS functioning, which may eventually lead to medical conditions.

The probability of such a dual placebo effect occurring and resulting in feelings or beliefs of success, in the context of the HRMTP, could be predicted to hinge on mutually high levels of hypnotic susceptibility in both the psychotherapist and patient. High HS is associated with increased openness to new experiences and intellectual and analytic exploration, the kind that psychodynamic and insight-oriented therapies are known to advance and engage in. The likelihood that an individual will seek out a psychologist or physician may be increased and predicted on the basis of an individual's level of HS. Couple a patient's high HS with a physician or psychologist's similar level of this trait, and both are

likely to interact cooperatively and in the context of a HS-mediated belief system that fosters confidence that treatment will work.

Again, on the basis of the normal distribution theorem, one would expect that about 15–30% of all patients and clinical practitioners to be high in HS. Should such individuals be paired through chance clinical encounters, one could predict that physician-driven placebo responses will occur in predisposed patients in up to 30% of all therapeutic relationships and efforts.

These hypotheses warrant investigation, since the implications of dual placebo-mediated clinical dynamics can have important consequences relative to intervention efficacy, morbidity, and even mortality—more so when pathophysiology goes undetected because a faulty belief system leads to false-positive or false-negative outcome. For example, it may be a mistake to assume that depression has been ameliorated if medical tests were not administered to substantiate such. To further illustrate: with the dual placebo effect in play, both the therapist and patient may be convinced that depression no longer exists, yet a test of heart-rate variability might reveal an SDNN or heart-rate variability index of less than 30, which can reflect depression-mediated reduced cardiac resiliency (Malik & Camm, 1995). In such an instance a dual placebo effect-mediated false-negative intervention conclusion may have been reached (no depression) yet underlying mind-body (ANS) responses suggest otherwise (low SDNN can be a symptom of depression or a residual consequence of this disorder; Lederbogen, Gernoth, Weber, Colla, Knies, Heuser, & Deuschle, 2001) or at least indicate that a cardiologic deficit may exist that would have gone undetected irrespective of whether a patient's depression was successfully treated.

A dual nocebo³ effect can also occur between a patient and practitioner who are both low in HS and high in RC, assuming that an individual who is high in RC would actually schedule and show up for an appointment. Should this occur (this is more likely in the course of involuntary hospitalization), both the practitioner and patient are apt to be hypercritical, skeptical, and overly analytical and diametrically opposite in their interactions, responding, and beliefs, as opposed to a dual placebo-prone clinician and patient who are high in HS.

3. A nocebo effect is the opposite of a placebo effect; it is marked by a strong belief that treatment will not work (Wickramasekera, 1988).

The low-HS and high-RC practitioner may order too many tests to the point of overkill because he or she is overcautious, and such may even be demanded by the high-RC patient, who needs more and more evidence to even remotely allay his or her skepticism and disbelief that illness or disease exists. In the intervention stage of such a relationship, both parties are likely to believe that a therapy or intervention will not work, the patient believing that there is nothing wrong, and the practitioner employing a vast array of treatment modalities before arriving at a diagnosis.⁴

Both the dual placebo and nocebo patient-practitioner dynamic can have practical and financial consequences, not to mention getting in the way of efficient patient evaluation and intervention. It further points to the need to assess patients and practitioners alike on HRMTP-PHO subject measures for clinical exploratory and research purposes.

PHO SUBJECT VARIABLE CONSTELLATION AND SELECT DISORDERS: PREDICTIONS

Based on known and hypothesized dynamics of constellations of HRMTP PHO subject variables, one could predict the following regarding their mediating relationship with various medical and psychological disorders.

Hypertension and Cardiovascular Diseases

High HS and N in the presence of real and/or perceived threat are expected to set off a cascade of psychophysiological responses, including heightened SNS activation at baseline and during apparently innocuous situations and settings. Due to the tendency to catastrophize and think the worse in regard to the future or perceived relevance of even minor visceral sensations that are associated with high N in the presence of high HS, SNS activation can escalate to such extreme levels so as to induce a full-blown panic attack. The increased focusing ability that marks HHS and that “normally” is or can be directed toward generating appropriate and performance-facilitative responses to carry out an im-

portant task, in the presence of real or perceived threat and concomitant symptoms, can lead to the obsessive attending to dysfunctional internal negative cognitions. Over time such chronic maladaptive psychophysiological responses can lead to a state of constant vasoconstriction and eventual hypertension, atherosclerosis, and CAD.

ADD and ADHD

HS is hypothesized to play an important role in the manifestation and attenuation of ADD. In the presence of high N, regardless of level of HS, one is more likely to observe an ADD hyperactivity component. The SNS hyperactivity that is associated with high N is expected to have an impact on cognition, specifically the ability to focus or attend to an intellectually demanding stimulus, such as a test or lecture. One way of alleviating the psychological discomfort that is associated with hyperreactivity/hyperactivity is to boost one's metabolic demands to achieve homeostasis. This can be best achieved through movement and may explain why individuals with ADD/HD who are athletes are capable of stellar performances and enhanced levels of selective attention that would not be expected (Carlstedt, 2008). Movement, especially at aerobic levels, may lead to better hemodynamic and endocrine self-regulation and concomitant brain responses that facilitate focus, motor control, and performance in action settings. Such would be predicted on the basis of the transient hypofrontality hypothesis (Dietrich, 2004). HS, consistent with its known and hypothesized characteristics, may also have a negative impact on attention as a function of high N, except that in contrast to the heightened focus on visceral symptoms and intrusive negative thoughts that are expected to occur in more classic psychophysiological disorders, in ADD, so-called surplus pattern recognition or hyperawareness of competing stimuli and the inability to hone in on task stimuli, may occur, resulting in poor performance.

Somatization Disorders, Anxiety/Panic Disorders, and Phobias

In this class of disorders, the effects of interactions between and among HRMTP PHO subject variables are hypothesized to be similar to those that are likely to occur in cardiovascular diseases. It is further predicted that chronic psychophysiological and anxiety disorders and the constant vasoconstriction that are associated with them can expedite the manifestation of CAD symp-

4. This may be good in many cases, especially in the realm of psychotherapy, where the dual placebo response effect may be pervasive and exceed what would be expected on the basis of the normal distribution, thereby reducing due diligence and making the diagnostic process less thorough.

toms and eventual onset of major organic cardiovascular events such as myocardial infarction. Moreover, while high N, which is a PHO psychophysiological mediator, has not, in isolation, been found to be associated with actual CAD (Geen, 1997), in the presence of high HS and resultant pervasive attending to negative internal N-generated cognitions, SNS activation may become more amplified and chronic to the extent that vasoconstriction and hypertension significantly exceed parameters that might have been discerned in previous studies that did not actually measure heart-rate variability and blood pressure.

While phobias, when manifested due to exposure to an inciting stimulus, are likely to exert a strong SNS response, they are not expected to affect CAD onset to the degree that other ANS-based disorders will, since it is assumed that the chronic SNS activation that is present at baseline in people who are high in N will be of a more sporadic and acute nature. In other words, having a phobia in the absence of high N and its chronic elevated SNS activity may not be as bad as having a phobia and being concurrently high in N, assuming that the phobia and neuroticism can be mutually exclusive, which remains to be established.

Hypochondrias

Hypochondriacs are likely to be high in HS and N but have such great fear of impending doom that they paradoxically refuse to ever see a physician, lest their fears be realized in the form of a diagnosis that brings with it a death sentence. Here too, as with neuroticism, previously it was thought that individuals with this disorder suffered from chronic psychological distress but rarely actually had any underlying disease of note. However, thinking in this area has changed, and it is now recognized that maladaptive, dysfunctional, and avoidant cognitions and behavior can have deadly consequences and that at some point a hypochondriac's worst nightmare might become a reality. This mental disorder, like anxiety, phobia, and psychophysiological conditions, is hypothesized to be neuroticism mediated, with symptom potentiation and chronicity exacerbated as a function of high HS.

Personality Disorders

Although HRMTP PHO individual difference subject variables appear to be most predictive and thought to have their greatest impact relative to specific medical and psychophysiological disorders, one measure in the HRMTP PHO triad—namely, RC—is hypothesized

to play a role in the development of various personality disorders. The self-preserving behaviors that are intended to reduce or eliminate psychological distress and boost self-esteem and confidence and the denial of and imperviousness to critique may also involve mechanisms similar to those that underlie narcissistic personality disorder and other socio- and psychopathic conditions. While the lack-of-empathy component of these ego-serving disorders would need to be established, meaning that high RC may be a necessary but not sufficient factor in the etiology of these conditions, the compromised ability to exercise self-criticism and engage in introspection that has been observed in high RC may transcend its medical relevance in mediating self-serving behavior that has moral and ethical consequences.

THE HRMTP AND INDIVIDUALIZED INTERVENTIONS: PSYCHOPHYSIOLOGICAL PSYCHOTHERAPY

The HRMTP approach to interventions relies heavily on physiological monitoring and has been referred to as psychophysiological psychotherapy (PPT; Wickramasekera, 1988). PPT is an integrative investigative procedure designed to analyze and reveal mind-body interactions and incongruence between patient verbal report and actual underlying ANS responses during psychotherapy. It is comprised of six stages of continuous physiological monitoring (Wickramasekera, 1994). The goal of PPT is to reduce ANS measures of threat perception and expand cognitive flexibility and adaptability in an attempt to reduce or eliminate somatic symptoms (Wickramasekera, 1994). The inhibition or disruption of dysfunctional cognitions or cognitive style and resultant perception of threat is addressed by hypnosis, self-hypnosis, other cognitive-behavioral methods, and/or biofeedback in an attempt to reduce ANS correlates of threat perception, including elevated blood pressure and cardiac hyperreactivity at baseline (Wickramasekera, 1994). It is based on the premise that PPT procedures will disengage subliminal and consciously consolidated dysfunctional memories, images, and emotions and thereby facilitate new and adaptive cognitive responses to real and perceived threat (Wickramasekera, 1988). PPT is indicated when patients presenting physical complaints without underlying disease cannot be effectively treated medically. It attempts to challenge formerly held notions and myths regarding the etiology of a patient's

somatic complaints by illuminating the extent to which a person's thoughts can mediate the development of symptoms (Wickramasekera, 1988).

PPT has been shown to be effective in treating a wide variety of somatic afflictions, including vasovagal syncope, headaches, clinical pain, Raynaud's disease, fecal and urinary incontinence, hypertension, and functional arrhythmias (Wickramasekera, 1988, 1994; Wickramasekera et al., 1996). Individualized applications of PPT and hypnosis are applied on the basis of the following HRMTP PHO subject variable constellations (Wickramasekera, 1993).

High HS, Low N, and High RC

While these types of patients tend to score in the normal or below range on widely used psychological tests (e.g., MMPI-2), they are at risk of "transducing" the perception of threat into somatic symptoms yet are often unaware of clinical pain and anxiety (Wickramasekera, 1993, p. 602). Patients exhibiting this profile are thought to have at least two mechanisms that suppress pain or fear from conscious perception, including high HS and high RC. In patients with this profile, who are adept at suppressing psychological stress, perception of stress, fear, and pain, chronic ANS hyperreactivity and concomitant vasoconstriction are thought to occur implicitly or unconsciously, as reflected in increases in blood pressure, very low frequency heart-rate variability, and/or electrodermal responses. This type of patient is considered vulnerable to serious medical disorders, including cancer and heart disease, especially during middle age, when unhealthy lifestyle factors can override whatever protective genetic attributes he or she may possess (Wickramasekera, 1993). According to Zillmer and Wickramasekera (1987), this patient will benefit the most from hypnotherapy with a psychodynamic or Gestalt orientation and delayed biofeedback.

Low HS, Low N, and High RC

This type of patient appears to be best served by a treatment modality that allows for a rapid and reliable shift into a state of low physiological arousal that facilitates the subjective perception of muscular and vascular changes (e.g., reduction of muscle tension, peripheral temperature manipulation). Consequently, immediate biofeedback is indicated, not least because it provides the low-HS and high-RC patient with objective feedback on mind-body interactions, which is often needed to convince the skeptical high-RC patient that something

is actually wrong. As previously mentioned, getting the low-HS, high-RC patient to participate in psychotherapy or medical interventions can be challenging. As such, the Trojan horse role induction method, a covert method of getting a patient with this profile to recognize the effects that emotions and cognitions can exert on psychophysiology, is used to help individuals who are low in HS and high in RC verbalize and experience changes in perception, which is necessary to participate in conventional psychotherapy (Wickramasekera, 1988). The failure to prepare and make the skeptical low-HS and high-RC patient aware that alterations in physiological arousal and somatic sensations can be cognitively induced often results in his or her termination of therapy (Zillmer & Wickramasekera, 1987).

High HS, High N, and High RC

Since high N and RC are characteristics of "explicit defensiveness" (i.e., repression), this type of patient requires a gradual approach to psychotherapy. Initially these patients should receive cognitive-behavioral therapy that focuses on somatic symptoms and the reduction of catastrophizing cognitions (Wickramasekera, 1993, p. 603). Once a trusting therapeutic relationship has developed, hypnotherapy (to which high-HS patients are amenable) can be introduced. Hypnotic suggestions that selectively focus on and retain positive memories and emotions should be used to restructure such patients' propensity to over-attend, especially to threatening cognitive stimuli (e.g., negative internal thoughts). After defensive barriers are reduced, hypno-analysis can be introduced to access unconscious resistance to greater levels of social intimacy, social support, and interpersonal vulnerability (Wickramasekera, 1993). Essentially psychotherapy and hypnotherapy with these patients strive to "boost psychological immunity" by increasing cognitive and behavioral adaptive coping skills and reducing "acting out" (Wickramasekera, 1993, p. 603).

High HS, High N, and Low RC

Because of its known and hypothesized characteristics and ANS correlates, it is expected that this HRMTP-PHO subject variable profile will be exhibited by the vast majority of patients who present due to mind-body symptoms and complaints, both in medical and psychological settings. High N, in the presence of high HS and low RC, and concurrent external or internal perception of threat, is thought to lead to excessive SNS activity. Over time, such chronic hyperactivation can lead to chronic symptoms, pain, psychological distress, and

eventual pathophysiology. Consequently, it is important that physicians and mental health practitioners use HRMTP-prescribed test instruments for diagnostic and intervention guidance to screen patients. This class of patient is very treatable because they are usually aware of or admit to having and are motivated to rid themselves of debilitating psychologically mediated symptoms (such as openness is associated with high HS). They are also amenable to most interventions, especially those that are imagery or hypnosis based. Monitoring their physiology during an intake session and ongoing psychotherapy will frequently reveal strong SNS spikes in response to directed questioning that conjures up memories or pain, symptoms, and often psychosocial mediators, such as a poor marriage or conflict with a coworker.

SYSTEMS OF PSYCHOTHERAPY: MATCHING INTERVENTIONS WITH PHO PROFILE

Table 9.1 pairs HRMTP PHO subject variable profiles with ideal intervention modalities. More neutral profiles in which middle levels of HS, N, and RC predominate

are more ambiguous regarding intervention amenability and must be teased out empirically. To that end, continuous monitoring of heart-rate variability during intake, therapy sessions, and in-vivo ecological settings (the real world) can help determine ANS responses to stressors and take precedence over the self-report-based instruments that the HRMTP uses.

It should be noted that these intervention modalities are recommended on the basis of their known ability to reduced excessive ANS-SNS activation through cognitive mediation or direct feedback (biofeedback). However, it should not be assumed that any intervention will work. The devil's advocate perspective, where the maxim "Show me the data" rules and determines an intervention's efficacy, should drive treatment strategies, since whenever self-report is involved in the assessment process, false positives and negatives are bound to occur. PHO and other profiling can be fallible. Consequently, an inappropriate treatment procedure can at times be applied to a misdiagnosed patient. Hence, ultimately, objective longitudinal, repeated predictor (mind-body measures such as heart-rate variability) and criterion outcome (changes in mind-body measures after intervention and/or performance or symptom differences) measures should be turned to for highest evidentiary guidance regarding profiling con-

9.1

HRMTP Constellation and Intervention Modalities

CONSTELLATION	INTERVENTION 1	INTERVENTION 2	INTERVENTION 3
HHS-HN-LRC (hypothesized to be the most common profile in medical-therapy context)	Hypnosis, self-hypnosis with biofeedback	Mental imagery with biofeedback	Physical exercise as an adjunct intervention in all high-N patients
LHS-HN-LRC	Biofeedback in office with cognitive component	Biofeedback at home with cognitive component	Biofeedback, real-world situation with cognitive component, physical exercise
HHS-LN-LRC (infrequent constellation)	Hypnosis, insight, talk therapy		
HHS-HN-HRC (rarest constellation since N and RC are orthogonal constructs)	Hypnosis, biofeedback	Physical exercise	Physical exercise

clusions and intervention selection decisions and for determining incongruence/congruence between practitioner intuition and patient self-report/test results. That is why ongoing psychophysiological monitoring during psychotherapy, at home and in the real world, should routinely be engaged in.

SUMMARY

The HRMTP is a multidimensional model composed of quantifiable measures including PHO individual difference risk factors, which in isolation or independently may be weak predictors of clinical outcome. However, in the presence of real or perceived threat, specific constellations of HS, N, and RC are hypothesized to be strong predictors of the complex mind-body interactions that have been shown to underlie various medical and psychological disorders. People at greatest risk of developing symptoms and eventual disease are those who are positive for all predisposing features and deficient in support systems and coping skills and have experienced multiple major life changes and/or hassles over a short period of time. Individuals at lowest risk are those who have none of the isolated risk factors and multiple effective support systems and coping skills (Wickramasekera, 1988).

Eating Disorders: Advances in Treatment and Management

Anthea Fursland
Hunna J. Watson
Bronwyn Raykos
Anna Steele
Sue Byrne

Eating disorders are notoriously difficult to treat and tend to run a chronic course. Although clinical practice guidelines suggest treatment by specialist services, in reality, most people with eating disorders will be treated in the community, where medical management remains with primary care (Turnbull, Ward, Treasure, Hershel, & Derby, 1996).

Of all mental illnesses suffered by women in Australia in 1996, eating disorders had the fourth-highest number of disability-adjusted life years, that is, “healthy” life years lost (Mathers, Vos, Stevenson, & Begg, 2000). Eating disorders have a profound impact on the individual’s life and are a substantial burden on health services across the world (Simon, Schmidt, & Pilling, 2005). Eating disorders are associated with serious medical complications and functional impairment. Approximately 70% of women with anorexia nervosa (AN) or bulimia nervosa (BN) report an anxiety disorder (Godart et al., 2003). Other common comorbid conditions include depression, body dysmorphic disorder, substance abuse, and personality disorders. Eating disorders in females typically emerge in early puberty, though binge eating

and purging behaviors tend to emerge in later adolescence (Stice, Killen, Hayward, & Taylor, 1998).

CLASSIFICATION OF EATING DISORDERS

Anorexia Nervosa

The lifetime prevalence of AN among females ranges from 1.4% to 2% (Wade, Bergin, Tiggemann, Bulik, & Fairburn, 2006) and the rate of occurrence in males is approximately one-tenth of that in females (American Psychiatric Association, 2000). The primary symptom of AN is an abnormally low body weight for age and height. In adults and older adolescents, this may manifest as weight loss in a person of a previously normal body weight. In children and younger adolescents, this may manifest as a failure to meet expected developmental milestones for weight gain. The disorder may be visible to the clinician due to the severely underweight and malnourished appearance of these patients. The

10.1 | DSM-IV-TR Diagnostic Criteria for Anorexia Nervosa

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (i.e., less than 85% of that expected, or failure to make expected weight gain during period of growth)
- B. Intense fear of gaining weight or becoming fat, even though one is underweight
- C. Disturbance in the way in which one's body shape is experienced, self-evaluation unduly influenced by body weight or shape, or denial of the seriousness of the currently low body weight
- D. In post-menarcheal females, amenorrhea (i.e., the absence of at least 3 consecutive menstrual cycles)

Specify type (for current episode):

Restricting type: has not engaged in regular binge-eating or purging behaviour

Binge-eating/purging type: has regularly engaged in binge-eating or purging behaviour (i.e., self-induced vomiting; misuse of laxatives, diuretics, enemas)

10.2 | DSM-IV-TR Diagnostic Criteria for Bulimia Nervosa

- A. Recurrent episodes of binge eating. A binge episode involves:
 - (1) eating, within approximately a 2-hour period, an amount of food larger than most others would eat in such circumstances
 - (2) a sense of loss of control over eating during this episode
- B. Recurrent inappropriate compensatory behavior in order to prevent weight gain (i.e., self-induced vomiting; misuse of laxatives, diuretics, enemas; fasting; excessive exercising)
- C. Binge eating and compensatory behaviours both occur, on average, at least twice a week for 3 months
- D. Self-evaluation unduly influenced by weight or shape
- E. Disturbances do not occur exclusively during episodes of anorexia nervosa

Specify type (for current episode):

Purging type: has regularly engaged in self-induced vomiting; misuse of laxatives, diuretics, or enemas

Nonpurging type: has used other inappropriate compensatory behaviors (e.g., fasting, excessive exercise) but has not regularly engaged in self-induced vomiting or misuse of laxatives, diuretics, enemas

diagnostic criteria for AN, taken from the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR;* American Psychiatric Association, 2000), are presented in Table 10.1.

Bulimia Nervosa

Lifetime prevalence rates of BN are reported to be between 1.1% and 4.6% (Wade et al., 2006) and, like AN, for males the prevalence rate is approximately one-tenth of that in females (American Psychiatric Association, 2000). The defining feature of BN is binge eating followed by compensatory behaviors designed to counteract the feared effect of binge eating—that is, weight gain. An episode of binge eating is defined as eating a very large amount of food in a discrete period of time coupled with a sense of loss of control during the episode. The onset of binge eating typically occurs after a period of sustained dietary restriction. Individuals will engage in a range of compensatory behaviors, including self-induced vomiting, laxative misuse, excessive exercise, or dietary restriction. The diagnostic criteria for BN, taken from the *DSM-IV-TR* (American Psychiatric Association, 2000), are presented in Table 10.2.

Diagnostic criteria for AN and BN are fairly consistent across the *DSM-IV-TR* and *International Statistical Classification of Diseases and Related Health Problems (ICD-10;* World Health Organization, 1992) classification systems. The primary difference is that *ICD-10* does not distinguish between restricting and binge-eating/purging types in AN, nor does it distinguish between purging and non-purging types in BN.

Atypical Eating Disorders/Eating Disorder Not Otherwise Specified

Persons who meet some but not all of the diagnostic criteria for AN or BN are classified by the *DSM-IV-TR* as “eating disorder not otherwise specified” (EDNOS). *ICD-10* classifies these persons under the more specific labels of atypical AN, atypical BN, or eating disorder unspecified. These cases tend to have a higher frequency

of clinical presentation than AN and BN (Fairburn & Bohn, 2005; Fairburn & Harrison, 2003).

The category of EDNOS covers a heterogeneous group of disorders. Although some may be thought of as sub-threshold variations of AN or BN, there is one distinct disorder, binge eating disorder (BED), that has been defined as a disorder in which recurrent episodes of binge eating occur at a frequency of at least twice per week for 6 months and in the absence of any inappropriate compensatory behaviors characteristic of BN (American Psychiatric Association, 2000). Other forms of disordered eating that are included in the EDNOS category include recurrent chewing and spitting out large amounts of food, and purging or other inappropriate compensatory behaviors in normal-weight individuals after eating small amounts of food. EDNOS cases should not be considered benign disorders, but just as serious and clinically significant as AN or BN.

Future Directions

Dissatisfaction with the current classification scheme for eating disorders is mounting for several reasons. First, there is clear overlap between eating disorder symptomatology across the eating disorders. Patients with any eating disorder diagnosis may engage in dietary restriction, binge eating, and compensatory behaviors, while overconcern with eating, weight, and shape is a common feature that is arguably the most important symptom of all the eating disorders (Fairburn, Cooper, & Shafran, 2003). Second, eating disorder diagnoses are unstable over time. Up to 50% of patients with eating disorders move back and forth from one diagnostic category to another, regardless of whether their initial diagnosis is AN, BN or EDNOS (e.g., Milos, Spindler, Schnyder, & Fairburn, 2005). Third, over 50% of patients seen in clinics meet criteria for EDNOS or an “atypical” eating disorder (Fairburn, Cooper, Bohn, O’Connor, Doll, & Palmer, 2007), making this group of patients the most common, if not “typical,” diagnosis seen in clinical practice.

A number of alternative classification systems have been proposed. One suggestion is to break down the classification of eating disorders further and to provide greater specificity. In AN, a functional staging system based on symptom severity in line with the classification of cancer has been suggested (Maguire et al., 2008). Within the category of EDNOS, BED has already been recognized as a distinct syndrome within EDNOS (e.g., Pull, 2004) and it is possible that it will be fully recognized as a distinct disorder in the next revision of the *DSM*. It has also been suggested that purging disorder should be recognized as a distinct eating disorder

(e.g., Keel, Wolfe, Liddle, de Young, & Jimerson, 2007; Wade, 2007). It has been defined as a disorder in which recurrent episodes of purging occur, on average, twice a week for 3 months; however, the purging is not associated with objective binge eating, nor does it occur exclusively during episodes of AN (Keel et al., 2007).

A more radical position is that eating disorders are best viewed in relation to symptomatology rather than diagnostic category and, as such, all the eating disorders should be classified under a single diagnostic entity, “eating disorder” (e.g., Fairburn, 2008; Waller, 2008). This “transdiagnostic” approach to conceptualizing the eating disorders is consistent with certain contemporary theories and interventions for eating disorders, which purport that common mechanisms are involved in the persistence of AN, BN, and EDNOS (e.g., Fairburn et al., 2003). These features include a dysfunctional scheme for self-evaluation (overvaluation of and control over eating, shape, and weight); extreme and persistent inflexible dietary restraint; and, in some patients, the use of other extreme methods of weight control such as self-induced vomiting, over-exercising, or laxative misuse. The transdiagnostic concept of eating disorders will be further addressed in the treatment section of this chapter.

ASSESSMENT

Eating disorders require immediate assessment and management due to the serious impact that poor nutrition and starvation syndrome (see box below) can have on growth, development, and physical health. This is particularly pertinent among children and adolescents, as poor nutrition can have a deleterious impact during this period of rapid physical growth.

Starvation Syndrome

Starvation exerts an extreme influence on physical, social, and cognitive functioning. The most profound demonstration of the effects of starvation was documented by Keys, Brozek, Henschel, Mickelson, and Taylor (1950) as part of an uncontrolled clinical experiment with Civilian Public Service volunteers in the 1940s. The aim of the study was to inform the development of postwar relief efforts for individuals in famine by creating a laboratory simulation of famine. Thirty-six volunteers embarked on a 12-week control period where

(continued)

baseline measurements were taken, followed by a reduced-calorie 24-week semi-starvation phase, and then various rehabilitation phases. The men were fit, healthy, psychologically stable, and cognitively sound. During the semi-starvation phase, startling deteriorations and abnormalities in biological and mental health occurred (the starvation syndrome). The men lost an average 25% of their body weight and heart volume shrank. Dietary restriction was associated with sleep disturbance, headaches, gastrointestinal difficulties (including bloating), edema, dizziness, reduced body temperature, and reduced heart rate. Restriction prompted bingeing and purging behaviors in some men. The men experienced several changes to cognition, including obsessing about food and eating, reduced concentration and alertness, and impaired judgment. Some became depressed, anxious, neurotic, irritable, socially withdrawn, and angry, and a minority began self-harming. As caloric intake and body mass increased, the starvation syndrome abated. This study suggested that many clinical features of eating disorders are the product of starvation, not pathognomonic to the illnesses. Many of the observed changes are amenable to normalization upon reinstitution of a suitable feeding program.

Assessment of eating disorders should be multidisciplinary and holistic, ideally encapsulating a medical and diagnostic assessment, family and child psychosocial interview (if appropriate), psychometric assessment, and dietetic/nutritional assessment. Subsequent management is best undertaken by a multidisciplinary team and based on a collaborative care model. For clinicians working in the community, it is essential to enlist the support of a psychiatrist or general practitioner to monitor the medical risk of the patient during treatment.

Patients with eating disorders often have high levels of shame and embarrassment, which may promote secrecy and denial (e.g., Heatherton & Baumeister, 1991). It is important to be cognizant of this when one is interpreting measures of eating disorder symptomatology. It is also important to remember that most psychometric tests used with children and adolescents are adaptations derived from adult measures and have not undergone full validation with child/adolescent samples. Key

10.3

The SCOFF Questionnaire

- (1) Do you make yourself Sick because you feel uncomfortably full?
- (2) Do you worry you have lost Control over how much you eat?
- (3) Have you recently lost more than One stone (14 lbs or 6.36 kg) in a 3-month period?
- (4) Do you believe yourself to be Fat when others say you are too thin?
- (5) Would you say that Food dominates your life?

From "The SCOFF Questionnaire: Assessment of a New Screening Tool for Eating Disorders," by J. F. Morgan, F. Reid, & J. H. Lacey, 1999, *British Medical Journal*, 319, pp. 1467–1468.

elements of a comprehensive assessment are detailed in Exhibit 10.1.

SCREENING INSTRUMENT DESIGNED FOR PRIMARY CARE AND GENERALISTS

The SCOFF (Morgan, Reid, & Lacey, 1999) is a five-question forced-choice (yes-or-no) screening measure for eating disorders (see Table 10.3). It requires no formal training and takes 2 minutes to administer, making it an ideal screening instrument for use in primary care or in any routine assessment when there is a concern over disordered eating. Patients score 1 point for every yes answer, and a score of 2 points warrants further investigation, as it indicates a likely case of AN or BN.

STRUCTURED INTERVIEWS DESIGNED FOR SPECIALISTS

Eating Disorder Examination (EDE)

The EDE (Fairburn, 2008; Fairburn & Cooper, 1993) has become the gold standard interview to assist in diagnosing eating disorders. It has demonstrated good reliability and validity (e.g., Guest, 2000), is widely used in clinical

10.1

Elements of a Comprehensive Assessment of Eating Disorders

MEDICAL AND PHYSICAL ASSESSMENT

Height, weight, BMI (computed as weight [kg] / height [m]³), percent expected BMI for gender and age, degree of protein-energy malnutrition, anthropometric measurements

Vital Signs

- Heart rate, blood pressure, orthostatic change, body temperature, capillary refill time

History

- Weight, medical, family psychiatric, birth, nutritional, medication (laxatives, diuretics, antidepressants, sleeping pills, anti-acne, prescription medication), and substance use or abuse

Gastrointestinal

- Hunger, constipation, nausea, diarrhoea, borborygmi, dysphagia, abdominal pain, scaphoid abdomen

Endocrinological

- Age at onset of menarche, menstruation pattern, amenorrhea

Cardiovascular

- Dizziness, fainting, bradycardia, heart palpitations

Dermatologic and Subcutaneous

- Lanugo, xerosis, cold sensitivity, dry and brittle hair, hair shedding, increased bruising, hypercarotenemia, purpura

Evidence of Vomiting

- Calloused hands ("Russell's sign"), recessed tooth enamel, parotid enlargement, glossitis, gingivitis, angular stomatitis

Laboratory and Radiologic Tests

- Levels of glucose, blood urea nitrogen, creatinine, electrolytes, magnesium, phosphorous, lipase, amylase, calcium, albumin, prealbumin, cholesterol, liver enzymes, muscle enzymes, complete blood count with differential and platelets, liver function tests, urinalysis, levels of thyroxine (T₄), free thyroxine, thyroid-stimulating hormone, triiodothyronine (T₃), reversed (rT₃) electrocardiogram, levels of estradiol (female), follicle-stimulating hormone (females), testosterone (males), luteinizing hormone (males), bone mineral density).

PSYCHOSOCIAL ASSESSMENT

Family background, family and patient psychiatric history, socioemotional development, past and current eating attitudes and behaviors, exercise habits, family functioning history, mental status examination, motivation for change, school history, impact of symptoms upon schooling

NUTRITIONAL/DIETETIC ASSESSMENT

Typical eating pattern (usual, 24-hour recall), current/past eating and nutrition history and changes associated with onset of the eating disorder, current/past weight history (current, highest ever, lowest ever, premorbid, perceived ideal, menstrual threshold), medication/supplement history, current/past food attitudes and beliefs, methods of weight control (caloric intake, binge episodes, purging behaviors), familial factors (attitudes, use of diet products)

DIAGNOSTIC AND PSYCHOMETRIC ASSESSMENT

See text

and epidemiological research, and has been translated into several different languages. The EDE assesses the frequency of eating disorder behaviors (including dietary restriction, binge eating, self-induced vomiting, and other compensatory behaviors) and eating attitudes (e.g., the overvaluation of weight and shape). It yields a total score and four subscales: restraint, eating concern, shape concern, and weight concern. It primarily focuses on the past 28 days, but some questions also focus on the past 3 months. The main limitations of the EDE are that clinicians require formal training to administer the interview, and administration of the interview can be time consuming, taking over an hour.

Child Eating Disorder Examination

The Child Eating Disorder Examination (Bryant-Waugh, Cooper, Taylor, & Lask, 1996) is the gold standard clinical diagnostic interview for children and younger adolescents and is appropriate for use with young people ages 8–14 years.

Structured Clinical Interview for DSM-IV (SCID-IV)

The Structured Clinical Interview for *DSM-IV* (First, Spitzer, Williams, & Gibbon, 1995) is a widely used diagnostic scale that includes assessment of eating disorder symptomatology. The SCID-IV provides information on whether or not an individual meets diagnostic criteria for an eating disorder. One disadvantage of the SCID-IV is that it does not assess the frequency or severity of individual symptoms, which renders it less useful in clinical practice.

SELF-REPORT INSTRUMENTS

Eating Disorders Examination Questionnaire (EDE-Q)

The EDE-Q (Fairburn, 2008; Fairburn & Beglin, 1994) is a 28-item self-report measure of eating disorder psychopathology over the past 28 days. It is essentially a modified self-report version of the EDE and has the same advantage of assessing the frequency and severity of key eating disorder behaviors, as well as core attitudes toward eating, weight, and shape. The EDE-Q has demonstrated good validity as a screening instrument for eating disorders compared to the EDE clinician interview, though it may underestimate episodes

of objective binge eating (Mond, Hay, Rodgers, Owen, & Beumont, 2004). It has excellent internal consistency and test-retest reliability (Luce & Crowther, 1999). The EDE-Q was originally designed for use with females age 14 years and older. However, normative data are available for younger females age 12 to 14 years (Carter, Stewart, & Fairburn, 2001). Other adaptations of the EDE-Q include a Youth EDE-Q for individuals age 12 to 17 years old (Goldschmidt, Doyle, & Wilfley, 2007).

Eating Attitudes Test (EAT)

The EAT (Garner & Garfinkel, 1979; Garner, Olmsted, Bohr, & Garfinkel, 1982) is a self-report measure of eating disorder attitudes that has been widely adopted in clinical and research settings. A 26-item and a 40-item version of this measure are available. The EAT has three subscales: dieting, bulimia and food preoccupation, and Oral Control. The EAT has been adapted for use across cultures and a child version, the Children's Eating Attitudes Test (Maloney, McGuire, & Daniels, 1988), has also been developed. The main limitation of the EAT is that it was originally developed as a measure of the symptoms of AN, so results should be interpreted with some caution in average or overweight individuals.

Eating Disorder Inventory–3 (EDI-3)

The EDI-3 (Garner, 2004) is a 91-item self-report measure of eating disorder psychopathology with a total score, 12 subscales, and 6 composite scores that measure constructs such as drive for thinness, bulimia, body dissatisfaction, and perfectionism. The EDI-3 has been validated for females age 13 years and older (Garner, 2004), and a modified version of the EDI, the Eating Disorder Inventory for Children (Garner, 1991), has been developed for use with younger children. The measure has been criticized on the basis that it is time consuming, does not provide a specific time frame and does not directly assess the frequency of some key eating disorder behaviors.

TREATMENT MONITORING AND OUTCOME INSTRUMENTS

Eating Disorders Examination Questionnaire

The EDE-Q (Fairburn, 2008; Fairburn & Beglin, 1994) has been shown to yield a reliable measure of change in eating disorder symptoms over time, even when com-

pared to the more time-consuming EDE clinician interview (Sysko, Walsh, & Fairburn, 2005). This makes it a good candidate for monitoring changes in eating disorder symptomatology across treatment.

Weight/BMI Charts

The practice of weighing patients at each treatment session and recording this on a weight chart is considered integral to cognitive behavioral therapy (CBT) for eating disorders. This practice provides information for the patient about the relationship between his or her eating and weight fluctuations and allows the clinician to monitor one aspect of medical risk. For adults, the use of body mass index (BMI) charts is recommended, as patients tend to be less fixated on BMI than they are on weight. Metric computation of BMI is calculated as weight (kg) / height (m)². Non-metric computation of BMI is calculated as weight (lb) / [height (in)²] × 703. The Centers for Disease Control and Prevention (2009) and the World Health Organization (1998) both advise that the healthy BMI range is greater than or equal to 18.5 and less than 25. However, in clinical practice with eating disorder patients, the healthy BMI range is generally considered to range from 20 to 25.

With children and adolescents, it is not helpful to rely on BMI alone to classify weight status, because BMI in this group varies markedly according to age, gender, and pubertal status. It is therefore recommended that clinicians use the international age- and gender-specific BMI centile charts, which take into account age and gender to determine weight status (Cole, Bellizzi, Flegal, & Dietz, 2000). On these charts, a BMI greater than the 90th centile is considered to be overweight, and a BMI less than 3rd centile is considered underweight.

ASSESSMENT OF READINESS TO CHANGE IN ANOREXIA NERVOSA

Patients with eating disorders are notoriously ambivalent about change. The Anorexia Nervosa Stages of Change Questionnaire (Rieger et al., 2000) is one promising measure that has been developed to assess readiness to recover from AN. It is a 20-item self-report measure that assesses the stage of change participants occupy with regard to anorexia symptomatology, with scores ranging from pre-contemplation to maintenance. The measure has been shown to demonstrate sound psychometric properties (Rieger, Touyz, & Beumont, 2002; Rieger et al., 2000).

ASSESSMENT OF RELATED PSYCHOPATHOLOGY

To obtain a comprehensive picture of the needs of patients with eating disorders, mood and other psychopathology that are commonly related to eating disorders also need to be assessed. It may be pertinent to consider measures of depression, anxiety, and self-esteem.

RISK FACTORS AND CAUSES OF EATING DISORDERS

When people with eating disorders are asked to identify the causes of their eating disorders they cite factors such as perfectionism, interpersonal stressors, dieting, body dissatisfaction, low self-esteem, life stressors, and family difficulties (Nilsson, Abrahamsson, Torbiörnsson, & Hägglöf, 2007). Scientists have incorporated these and other personality, cognitive, behavioral, and social factors into theoretical models and have integrated additional specific theories of genetics, neurochemistry, neurobiology, and culture.

Risk factors are characteristics, events, or experiences that have been correlated with a disorder. While they do not prove a causal association, they give clues about the etiology of a disorder and are important for prevention and for targeted intervention of high-risk groups. Table 10.4 summarizes specific risk factors for AN, BN, and BED, along with non-specific factors that increase vulnerability to eating disorders in general.

Genetics

Familial transmission of AN, BN, and BED has been firmly established. Twin studies have produced moderate to high heritability rates across all eating disorders (Bulik, Berkman, Brownley, Sedway, & Lohr, 2000; Javaras, Laird, Reichborn-Kjennerud, Bulik, Pope, & Hudson, 2008). Risk of AN is much higher in female relatives of a person with AN than in those with no relative with AN, and higher in relatives of BN than in controls (Strober, Freeman, Lampert, Diamond, & Kaye, 2000). Most implicated genes are within biological systems that regulate food intake, appetite, metabolism, mood, and/or response to pleasure and reward. These biological systems include serotonin, dopamine, neuropeptide, catecholamine, opioid, and others (for a recent review, the reader is referred to Klump & Culbert, 2007).

Biology and Neurochemistry

The high genetic contribution to eating disorders suggests that biological and neurochemical substrates are likely candidates in the genesis of the disorders. Serotonin has received the most attention, as it has an established role in the regulation of eating behavior and mood and is linked to eating disorder risk factors such as traits of harm avoidance, tendency to obsess, and impulsivity. Individuals with eating disorders tend to show serotonin dysregulation, with no clear unidirectional tendency for specific eating disorders (Steiger, 2004).

Norepinephrine is known to trigger feeding behavior even in instances of satiation and is involved in the regulation of mood and metabolic rate. Disturbances in norepi-

nephine function are seen in both AN and BN (Halmi & Yum, 2007). Dopamine underpins the brain reward pathway in the limbic system. Release of this neurotransmitter during activities such as eating, sexual activity, and the use of certain substances produces a pleasurable affective state. Pathophysiology in this system has been identified in AN and BN, yet the research is inconsistent, again specifically in regard to directionality.

The gastrointestinal tract and adipose tissue generate hormones and other substances that regulate metabolism and appetite. Research with respect to eating disorders has focused on the hormones leptin, adiponectin, and resistin, and the peptides ghrelin and peptide YY (Favaro, Monteleone, Santonastaso, & Maj, 2008).

Overall, biological etiology is not well mapped, as most study samples are conducted during illness

episodes or post-recovery, rather than prior to onset of the condition. There are also physiological and behavioral changes associated with starvation, binge eating and purging, and other eating disorder-related behaviors, which confound scientific investigations.

Personality and Temperament

AN and BN are closely associated with the personality traits of perfectionism, obsessive-compulsiveness, neuroticism, negative emotionality, harm avoidance, low cooperativeness, ineffectiveness, and traits associated with avoidant personality disorders (Cassin & von Ronson, 2005). AN is further associated with low novelty seeking, high constraint, and persistence, and BN with high impulsivity, sensation seeking, novelty seeking, and traits associated with borderline personality disorder. Few studies have examined BED, though present evidence indicates that these individuals are more similar to those with BN than AN or healthy controls. Psychometric studies have largely focused on acutely ill individuals, yet starvation induces depression, anxiety, rigidity, irritability, and obsessiveness. Preliminary evidence suggests that these traits may persist after recovery, consistent with an etiological framework, yet there is no strong evidence that these traits cause eating disorders.

Familial Influences

Individuals with AN, BN, and BED may be more likely to come from families that emphasize the importance of weight and shape. Mothers with clinical or subclinical eating disorders transmit unhelpful attitudes and behaviors and identify their daughters as less attractive and as requiring more weight loss than comparison mothers or the daughters themselves (Hill & Franklin, 1998). If mothers engage in dietary restriction—one of the most important precursors to eating disorder development—daughters are significantly more likely to do so and to pursue additional methods of weight and shape control (Benedikt, Wertheim, & Love, 1998). This relationship is independent of the daughter's body weight. Critical comments from family members about weight, shape, and eating are a significant risk factor for BED (Fairburn et al., 1998). As is common to other psychiatric disorders such as schizophrenia and OCD, a family environment that is critical and invalidating; has poor cohesion and increased conflict; and is characterized by parental control, intrusiveness, and enmeshment may comprise a non-specific diathesis (Polivy, Herman, & Boivin, 2004).

Sociocultural Influences

Sociocultural theories are particularly good at accounting for the predominance of eating disorders among females in Western cultures. Abnormal eating attitudes and eating disorders in non-Western countries are gradually increasing as globalization and exposure to Western media rise (Makino, Tsuboi, & Dennerstein, 2004). The most salient cultural standard for female beauty in Western cultures is thinness. For most girls and women, this standard is largely unrealistic and unattainable. While the higher prevalence of eating disorders in Western versus non-Western countries is firmly established, it is important to note that only a small proportion of individuals in Western countries actually develop a clinical eating disorder. To account for this, Stice (1994) developed a model of sociocultural transmission, which also contains cognitive and behavioral components. It proposes that internalization of the thin ideal produces body dissatisfaction, producing negative affect and dietary restraint, which in turn increases the risk of eating disorder development. Cross-sectional and longitudinal studies have validated many features of this model, and reversal of certain mechanisms has been observed to have a positive effect on mechanisms further down the model chain. Urban living has been reported to be a risk factor for BN, but not AN (van Son, van Hoeken, Bartelds, van Furth, & Hoek, 2006).

COGNITIVE-BEHAVIORAL MODEL

The cognitive-behavioral model emphasizes cognition as a moderator of distressed emotional states and abnormal eating behaviors. Individuals with eating disorders differ from normative samples on a range of cognitive dimensions, including core schemas for weight and shape, perfectionism, tendencies to obsess, dichotomous thinking, rigidity, impaired set-shifting ability, and impulsivity (Polivy & Herman, 2002). A difficulty with research on cognitive-behavioral theories is that most studies are cross-sectional or conducted during acute illness episodes, posing problems in the interpretation of causation. It is well known that starvation can exacerbate psychological changes (Garner, 1997; Keys et al., 1950). Cross-sectional research can do little to separate the influence of eating disorder sequelae from postulated etiology. Even if cognitive markers differentiate premorbid individuals from normative individuals, there is inherent difficulty in explaining the origin of the dysfunctional cognition. The cognitive-behavioral model ascribes the cause of cognitive dysfunction to developmental events, heredity, biology, personality, and

sociocultural factors. While cognitive-behavioral theory does not provide a compelling account for the etiology of eating disorders, this theory has informed the leading model of disorder maintenance, particularly with respect to BN, where evidence-based treatments have been derived directly from the model.

MODELS OF EATING DISORDER MAINTENANCE

Cognitive-behavioral models of maintenance and modification have been described for adults with AN (e.g., de Silva, 1995; Fairburn, Shafran, & Cooper, 1998; Freeman, 1995; Garner & Bemis, 1985), BN (e.g., Fairburn, 1981; Fairburn, Cooper, & Cooper, 1986), and BED (Castonguay, Eldredge, & Agras, 1995). The psychopathology underlying the disorders shows great similarity and has resulted in considerable overlap among the models. This issue relates strongly to the debate underway regarding the inadequacy of the diagnostic nomenclature of the eating disorders.

Consequently, a transdiagnostic extension of the cognitive-behavioral model has been proposed by Fairburn et al. (2003) to account for the persistence of the full range of eating disorders. Because this model contains elements of previous models and its development has been informed by empirical studies, this model will be summarized here.

The core psychopathology of the transdiagnostic model is consistent with previous models and includes overvaluation of controlling eating, weight, shape; strict dieting and other weight-control behavior; binge eating; and compensatory behaviors including vomiting/laxative misuse. Through life experiences, individuals with eating disorders come to overvalue control over eating, weight, and shape in relation to their identity rather than developing a balanced view that incorporates other dimensions, such as relationships, work, activities, family, and parenting. This leads to behavior focused on controlling eating, shape, and/or weight. Rigid, inflexible behavior in this context is difficult to maintain. The breaking of strict dietary rules is interpreted as a loss of self-control, which may precipitate temporary abandonment of rules and, in some individuals, binge eating. Binges often occur in the context of a psychosocial stressor or negative affective state and reinforce further eating disorder behaviors by temporarily neutralizing negative affect. Compensatory purging behaviors are maintained by the belief that purging will prevent weight gain, further reinforcing binge eating.

CLINICAL GUIDELINES FOR THE TREATMENT OF EATING DISORDERS

Developing effective treatments for eating disorders remains a pressing task. There exists limited convincing evidence to dictate how best to provide treatment for these individuals. Despite this, various clinical guidelines have been published. These include the National Institute for Clinical Excellence (NICE; 2004) guidelines for eating disorders developed in the United Kingdom, the American Psychiatric Association's *Practice Guideline for the Treatment of Patients with Eating Disorders* (2006), and the Royal Australian and New Zealand College of Psychiatrists' "Clinical Practice Guidelines for the Management of Anorexia Nervosa" (Hay & RANZCP Royal Australian and New Zealand College of Psychiatrists, 2004). A summary of the NICE treatment recommendations is presented in Table 10.5.

Outcome for adults with AN does not appear to have improved over the second half of the 20th century (Steinhausen, 2002). A recent review of randomized controlled trials concluded that evidence for AN treatment is weak (Bulik, Berkman, Brownley, Sedway, & Lohr, 2007). Although the NICE guidelines do not specify a psychological treatment to use with these clients, they do suggest that clinicians may consider using elements of CBT, cognitive analytic therapy, interpersonal psychotherapy, or focal psychodynamic therapy. For children and adolescents with AN, the NICE guideline suggests the use of a family-based psychological intervention.

For adults with BN, the picture is more promising. Cognitive-behavioral therapy for BN (CBT-BN) has been recognized in the NICE guidelines as a treatment of choice, and if individuals are non-responders, interpersonal psychotherapy is a possible alternative. Although NICE cites strong empirical support for CBT-BN with adults, it offers only tentative recommendations for children and adolescents.

For the atypical eating disorders, very few treatment trials have been conducted. One exception is BED, where the NICE guidelines recommend CBT as a first step in treatment. For other variants of EDNOS, NICE recommends treatment for the disorder that most closely resembles the presenting problem.

Inpatient settings are advisable when the eating disorder is accompanied by a high level of medical instability (see Exhibit 10.1). Inpatient treatment of AN often involves weight restoration without targeting specific psychological maintaining factors related to eating disorder psychopathology. When patients return to the home environment, it is often very difficult for them to maintain

their weight if careful monitoring is not implemented by a clinician, and for some patients this will result in a relapse of symptoms and subsequent weight loss. To ensure progress made in hospital is maintained, inpatient and outpatient services must liaise carefully and ensure

10.5

Summary of NICE Recommendations

Anorexia nervosa

- The majority of people with AN can be managed in an outpatient setting. They should receive psychological treatment from a service that is experienced in treatment and risk assessment of people with eating disorders.
- Some people with AN will need inpatient treatment. They should be admitted to a facility that provides psychosocial interventions and skilled implementation of refeeding.
- Children and adolescents with AN should be offered family interventions that focus on the eating disorder.

Bulimia nervosa

- An evidence-based self-help program should be considered as a first step for patients with BN.
- A trial of an antidepressant drug may be considered as an alternative or an adjunct to evidence-based self-help program for adults with BN.
- Adults with BN should be offered cognitive-behavior therapy for BN (CBT-BN), a specifically adapted form of cognitive-behavior therapy, lasting 16–20 sessions over 4–5 months.
- Adolescents with BN may be offered CBT-BN adapted to suit their age and developmental level. The family should be included where appropriate.

Atypical eating disorders

- Adults with binge eating disorder should be offered cognitive-behavior therapy for binge eating disorder, a specifically adapted form of cognitive-behavior therapy.
- There is a lack of evidence for the treatment of atypical eating disorders (other than binge eating disorder). The clinician should consider following the treatment recommendations for the eating disorder that is most similar to the patient's eating problem.

that the individual's psychological needs continue to be met regardless of weight status.

Alongside treatment for an eating disorder, comorbid conditions (e.g., depression, anxiety disorders) often require simultaneous treatment. Clinicians need to be equipped to manage these comorbid symptoms, or to refer patients to a specialist in that area where necessary.

Given the seriousness and complexity of eating disorders, and the widely accepted view that they remain extremely difficult to treat, it is of utmost importance that outcome studies continue to identify effective modes of treatment. Clinicians are encouraged to remain up to date with the research literature, given the constantly evolving nature of the field.

ADVANCES IN EVIDENCE-BASED TREATMENT OF EATING DISORDERS

Treatment trials around the world are currently evaluating innovative treatments for eating disorders in an attempt to improve upon the current evidence-based guidelines. Two of these outpatient approaches are described in the following section.

Family-Based Therapy for Children and Adolescents

The family-based (“Maudsley”) approach to treating eating disorders in children and adolescents originated from work at the Maudsley Hospital in London and has been tested mostly with individuals with AN, rather than BN. Family-Based Therapy (FBT) has been manualized by Lock, Le Grange, Agras, and Dare (2001). Treatment involves 3 phases, usually distributed over the course of a year. In phase 1 parents are strongly encouraged to take control of the child's eating until there is evidence of steady weight gain and child compliance with the installed regime. Phase 2 involves negotiating a new pattern of relationships where the responsibility for eating is shifted back to the child, with the goal of restoring pre-morbid physical health and reducing environmental tension. Phase 3 addresses developmental issues and termination.

FBT for children and adolescents with AN has been evaluated in a variety of controlled trials (e.g., Eisler, Dare, Hodes, Russell, Dodge, & Le Grange, 2000; Eisler, Dare, Russell, Szumukler, Le Grange, & Dodge, 1997; Geist, Heineman, Stephens, Davis, & Katzman, 2000). Outcomes are promising and indicate significant weight gain and

improvement in eating disorder psychopathology. This is a particular advance in the field, given the noted difficulty of treating AN in adults, where treatment trials have yet to yield such positive results. Fewer treatment trials have been conducted to test FBT in children and adolescents with BN, though one controlled trial showed good clinical outcome compared to supportive psychotherapy (Le Grange, Crosby, Rathouz, & Leventhal, 2007), and another showed comparable outcomes compared to CBT guided self-care (Schmidt et al., 2007).

Transdiagnostic Treatment for Adults

Christopher Fairburn and his colleagues at the University of Oxford have developed a transdiagnostic theory of the processes that maintain all forms of eating disorders. This theory was based on the observation that AN, BN, and EDNOS share many distinctive clinical features (Fairburn et al., 2003). The transdiagnostic treatment based on this theory involves an enhanced version of cognitive behavior therapy for eating disorders (CBT-E), and a treatment guide has recently been published (Fairburn, 2008). CBT-E involves four stages of treatment. The focus of stage 1 is behavioral change, with interventions such as self-monitoring, psychoeducation, weekly weighing, regular eating, and a personalized formulation. Stage 2 involves a review of progress, where the therapist and patient jointly identify areas of improvement and barriers to progress in treatment to date, revise the formulation if necessary, and plan for the next stage of treatment. Stage 3 focuses on addressing the processes that maintain the eating disorder (i.e., the core psychopathology of eating disorders: overvaluation of control over eating, shape and weight). This is considered the main body of the treatment program. Stage 4 focuses on the maintenance of progress and relapse prevention. The therapist and patient explore the strategies required to manage unhelpful eating-related thoughts and behaviors in the future.

Initial post-treatment results for this transdiagnostic approach are very encouraging. In a randomized controlled trial involving two UK sites ($n = 154$, consisting of those with a BMI of $> 17.5 \text{ kg/m}^2$), 66.4% of treatment completers reduced their eating disorder psychopathology to within one standard deviation of community norms on the EDE (Fairburn et al., 2009). In an open trial at a public health clinic in Western Australia ($n = 119$, consisting of patients from across all three *DSM-IV* categories of eating disorders), 62.5% of treatment completers ended treatment with EDE-Q scores

within one standard deviation of community norms (Fursland & Byrne, 2009).

IMPLEMENTING ENHANCED COGNITIVE BEHAVIOR THERAPY

In this section we discuss the practical implementation of CBT-E in an outpatient clinical setting (for a complete guide, see Fairburn, 2008). CBT-E is designed to be applicable to all eating disorders. Fairburn designed a 20-session program for individuals with a BMI greater than 17.5 kg/m^2 and a 40-session program for individuals with a BMI less than or equal to 17.5 kg/m^2 . However, in our practice we tend to offer the shorter version of the treatment to individuals with a BMI greater than 18.5 kg/m^2 , as we find that people of lower weight need more extensive work. One aspect that differentiates CBT-E from earlier versions of CBT for eating disorders is the notion of metacognitive awareness. This “decentered” stance helps patients develop a “helicopter view” of their eating disorder, whereby they are able to distance themselves from the disorder and change their relationship with it.

CBT-E Assessment

Usually two to three assessment sessions are needed, each of 60 to 90 minutes, to identify the full extent of the eating disorder psychopathology and to establish a therapeutic alliance. Many patients with eating disorders, especially those with AN, are terrified of change. Those with low weight fear achieving normal weight (which they perceive as “getting fat”) and those in the healthy weight range are afraid of gaining weight and becoming overweight if they relinquish their disordered eating behaviors.

Height and weight are measured to provide a baseline BMI; BMI is monitored throughout treatment. It is recommended that some psychometric measures of depression, anxiety, and eating disorder psychopathology be obtained. Other useful measures include self-report measures of self-esteem and quality of life. For eating symptoms, we recommend the EDE-Q. The EDE-Q not only offers information on the patient’s presenting symptomatology, but provides a baseline measurement that can be used for monitoring treatment progress and outcome.

As with all outpatient treatment of eating disorders, clinicians delivering CBT-E must ensure that the patient’s physical health is monitored by a medical practitioner, which may require communicating with the patient’s general practitioner and/or any other member

of the treatment team. A summary of the assessment should be sent to the physician who is responsible for medical monitoring.

By the end of the assessment it should be clear whether CBT-E is an appropriate treatment modality for the patient. Contraindications to starting the treatment include barriers to establishing a therapeutic alliance (e.g., clear refusal by the patient to engage in treatment, or a predictable absence of either the therapist or patient during the next 4–6 weeks) and therapy-interfering circumstances (e.g., serious medical risk, either due to extremely low weight [BMI <14], or excessive purging, or precipitous weight loss; suicide risk or untreated major depression or substance abuse that would interfere with treatment; life events such as recent bereavement or imminent university examinations). Previous lack of success with well-implemented CBT-E is also a contraindication.

If CBT-E is indicated, patients receive a description of the therapy to orient them to the treatment. They are informed of the likely number of sessions (20 sessions for normal-weight clients and 40 sessions for low-weight patients) and the length of each session (50 minutes), and that for the first 4 weeks, sessions will be twice weekly. Weight is measured weekly and each session follows an agenda. Treatment is collaborative, with the patient and therapist working as a team for the patient's benefit. Between-session tasks (especially self-monitoring) are vital, and the patient must be willing to work hard between sessions—for the full 168 hours of the week, not just during the sessions. Treatment is present and future oriented and focuses on the maintaining factors. Describing CBT-E also gives the therapist the opportunity to instill hope. The patient learns that CBT-E developed from CBT for BN, the leading evidence-based treatment for that disorder, and that approximately two-thirds of patients who complete CBT-E recover.

Parents or significant others can be included in the assessment. This is especially desirable for young people who still live at home. If others are to be included, it is important to convey that the therapy is for the benefit of the patient, and that any family involvement will be for the benefit of the individual. Confidentiality must be respected, and this should be made clear to the patient and the family involved.

Marie, a single woman of 25, presented with a 9-year history of low weight and a current BMI of 15.2. Assessment revealed that throughout Marie's childhood her mother had been dieting and

had always fed Marie “healthy” foods. As Marie entered puberty in her early teens, she gained some weight and as a result felt unhappy. At the age of 15, she began dieting with a friend. When she lost weight, she received positive comments from her mother and a boy that she liked. Although her friend gave up dieting, Marie persisted, believing that if she became thinner she would feel better about herself and feel happy. It was only months later that her parents started worrying about the weight loss. They took her to her doctor, who informed her that she had “healthy low blood pressure” and advised her to stop dieting. However, she continued restricting food intake and 6 months later collapsed at school. She was admitted to hospital with a BMI of 15.5. She was discharged 3 weeks later with a BMI of 17, having gained 8 lbs. She finished school and started law school, but she found it hard to cope with the pressures. She was unable to continue because of anxiety and impaired concentration, and because her studies were interrupted by further admissions to hospital. At the time of the assessment she was living with her parents and working part-time in a cafe. She was not in a relationship and had few friends. Her symptoms included dietary restriction, with twice-weekly binge eating and self-induced vomiting. She ran 5 miles every day and attended the gym 3 times per week.

CBT-E Stage 1 (Sessions 1–7; Twice Weekly)

Addressing Ambivalence and the Process of Change

Many patients with eating disorders who present for treatment have been pressured to relinquish unhealthy eating-related and weight-control behaviors by concerned others. Family, friends, and health professionals have typically informed patients that they are endangering their health and that it would be better for them if they adopted healthy behaviors. While individuals with eating disorders are usually aware of the truth in these statements, the advice has little impact on their behaviors. CBT-E encourages patients to consider the role and functions that the eating disorder fulfills in their lives, and the advantages and disadvantages of

having the disorder. Patients are asked to list both the pros and cons of recovering from their disorder, and also the pros and cons of remaining the same. Many patients have never been asked what positive benefits they derive from their eating disorder, and they find this exercise extremely validating. It also instigates the process of helping patients distance themselves from the eating disorder.

In-Session Weighing

Between the assessment and the start of treatment, the therapist plots the patient's BMI on a graph. For someone of average weight, it is helpful to mark on the graph horizontal lines corresponding to a BMI of 20 and a BMI of 25: the healthy weight range. For someone of low weight, it is helpful to draw a horizontal line, which corresponds to a BMI of 20, and a dotted line corresponding to a BMI of 19, as these patients often find it easier to see a BMI of 19 as an interim step to health (see Figure 10.1).

In-session weighing is a non-negotiable aspect of treatment. Patients are asked to cease weighing themselves at home during the course of treatment. Many people with eating disorders weigh themselves several times a day, ostensibly to reassure themselves either that they have not gained weight or that they are losing weight. In reality, weighing rarely results in reassurance and more often results in dissatisfaction. Nonetheless, the thought of reducing weighing behavior provokes significant anxiety, so it is important to provide a sound rationale for this: frequent weighing results in preoccupation with weight and provides misleading information, but avoidance of weighing is also problematic, as there is no feedback to confirm or disconfirm fears of weight gain. In-session weighing allows patients to receive clear information about any weight changes as they are changing their eating habits. It also provides an opportunity for the therapist to help patients interpret any weight change, which is useful, as people with eating disorders are prone to misinterpret small shifts in weight, and this precipitates further dietary restriction or weight-control behaviors.

Patient and therapist should spend time discussing interpretation of the weight graph. It should be explained that no conclusions can be drawn from a single measurement, as weight fluctuates naturally (depending on bladder and bowel activity, intake of food and liquid, dehydration, plus other factors such as stage in the menstrual cycle and thickness of clothes). A series of 4 weights needs to be examined in order to identify a real trend in BMI change. It is helpful to talk about

“weight regain” rather than “weight gain” (for those who are underweight), and also to talk about “the number on the scale” rather than “your weight,” as this is another way of helping patients distance themselves from the eating disorder.

Patients are weighed at the start of each session (see Figure 10.1). This is usually an anxiety-producing exercise. Obtaining a weight measurement at the start of the session allows the patient and therapist time to discuss, explore, and reduce anxiety before moving on to other agenda items.

Self-Monitoring

Some patients will have been asked to do some kind of monitoring of food intake, either by a dietitian or a previous therapist. It is important to note that the self-monitoring in CBT-E is of a different nature, and an integral part of the therapy. While many therapists claim that patients are reluctant to complete food records, it is our experience that a committed therapist who believes in the usefulness of recording will be able to obtain cooperation by offering a thorough rationale.

Self-monitoring should be done in real time. This ensures better accuracy of the information collected and allows the patient to develop increased awareness in the moment. Self-monitoring in the moment is introduced as a vital technique from which both patient and therapist learn the link between eating behaviors, weight control behaviors, moods, thinking, and situations. Becoming aware of their behaviors, thoughts, and feelings in the present moment allows patients to distance themselves from these behaviors. As a result, it becomes possible for them to begin to make choices about actions that they thought were automatic and beyond their control. It is helpful to talk about “looking for clues” in the monitoring records, like detectives working as a team to learn about the eating patterns in order to facilitate change. It is useful to help patients identify the real difficulties they might face (e.g., completing their records while at work or when out with others) and to encourage them to strategize and problem solve. Some solutions that patients have generated include texting themselves, sending themselves e-mails, and carrying a folded monitoring sheet (or sticky note), which they can complete during a break in their daily activities.

Self-monitoring should be reviewed at every session by the therapist and patient together. Without this, there is little reason for the patient to continue what is an onerous task. The first recordings need the most time, and they should be reviewed not just for the content (the eating patterns) but for how well the patient

Figure 10.1 Session-by-session BMI chart.

10.2

Marie's Self-Monitoring Record

MY SELF-MONITORING RECORD					
Day <u>Monday</u>			Date <u>07/22/08</u>		
Time	Food and liquid intake	Location	Binge (*)	Vomit (V)/ Laxative (L)	Situation/thoughts/feelings
7:30am	1 mug of black coffee ½ cup All-Bran with ½ cup fat-free milk	Kitchen table			7:00am: Weighed myself. 97 lbs. Less than last night. Pleased.
10:00 am	1 can of diet Pepsi	At work			
12:00 pm	Mug of coffee	At work			
2:30 pm	1 can diet Pepsi	At work			Only coffee for lunch, trying to make up for breakfast.
5:45pm	1 piece of toast	kitchen			
5:53pm	1 large glass wine	In my room			
5:59pm	5 pieces of toast & margarine		*	V	6.05pm: Weighed myself. 99 lbs Disgusted with myself.
6:15pm	1 cold apple pie		*		Vomited. Depressed about binge. Resolved not to eat for the rest of the night. Felt awful, couldn't look in the mirror. Vomited. I couldn't eat downstairs in front of my parents.
7:30pm	1 packet of chocolate chip cookies		*	V	
9:40pm	1 fat-free yogurt				
9.55pm	1 packet chocolate chip cookies		*		
				V	When they were watching TV I snuck into the kitchen and grabbed the cookies. I hate myself so much. My weight will have gone up SO much but I'm too scared to look. Vomited.
Exercise (time and type): None! I'm a fat lazy slob and I hate myself. I am disgusting					

was able to record in real time. The therapist should offer positive feedback and validation of the patient's efforts, together with suggestions regarding ways to improve the quality of the recording.

See Exhibit 10.2 for an example of a self-monitoring record completed by Marie early in treatment. Note the lack of regular eating and the narrow choice of foods.

The Formulation

Many therapists will be familiar with the idea of constructing a case conceptualization. The CBT-E formulation is similar, but it is an individualized pictorial depiction of the factors maintaining the patient's eating disorder (see Figure 10.2). It is created jointly, early in treatment and often in the first session; a copy is given to the patient, and a copy is placed on the table during each subsequent session. It is always a work in progress, with additions and changes made as more relevant information comes to light.

The formulation is useful in several ways. First, it explains the vicious cycle of the eating disorder. This helps patients make sense of the links between their thoughts and feelings (especially those related to the overvaluation of weight/shape) and their eating disorder behaviors (e.g., dietary restriction). It also highlights the link between dietary restriction and binge eating. Second, it identifies areas to target in treatment. Third, patients feel understood and may offer a response such as "Yes, that's me!" Lastly, it helps patients distance themselves from the eating disorder. As they take a conscious step back from their usual experience and acknowledge the self-perpetuating cycle, they often begin to see their behaviors are not an integral part of themselves, but a set of behaviors that can be changed.

Regular Eating

Regular eating is the foundation of all healthy changes in eating patterns, and its importance in eating disorder treatment cannot be overstated. Regular eating means

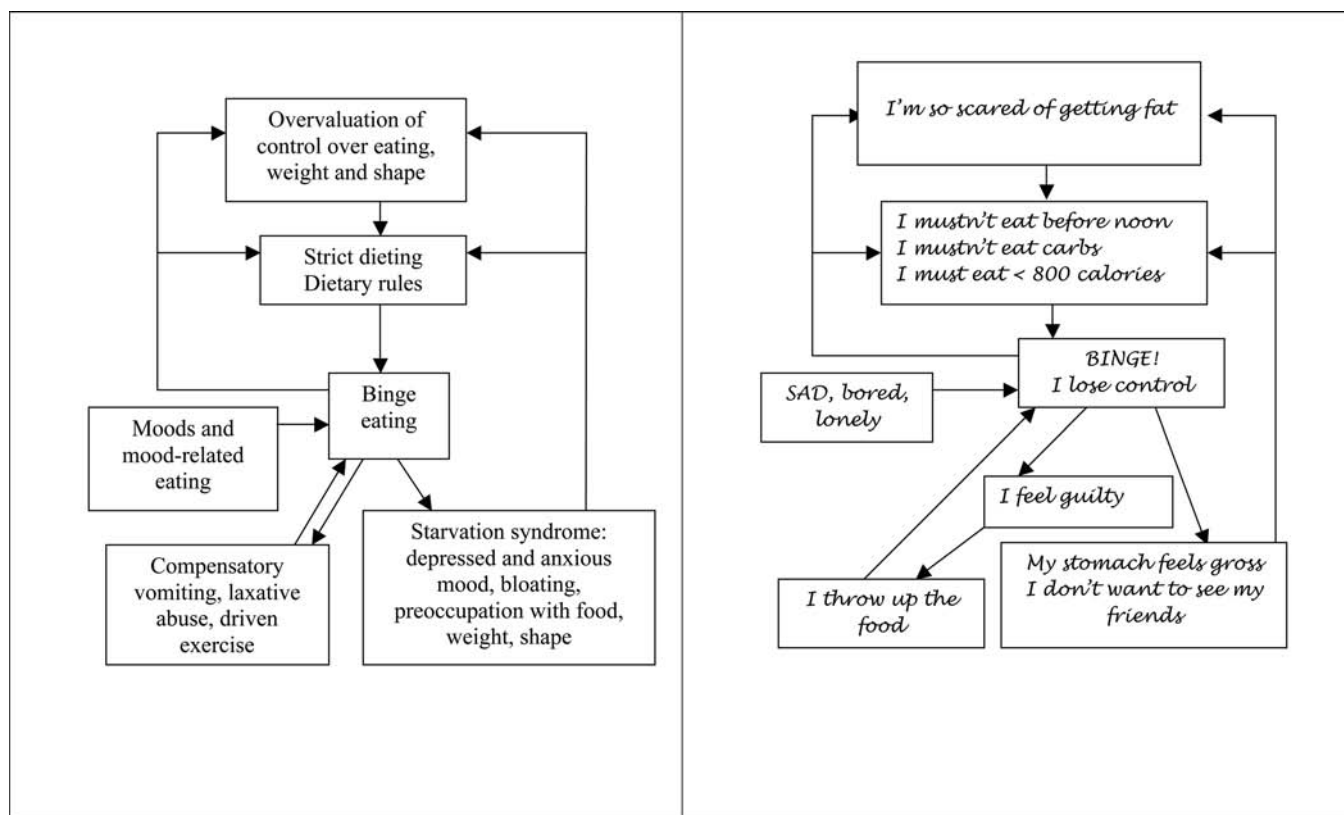

Figure 10.2 CBT-E formulation of mixed disorder (starvation, binge/purge) and Marie's personalized formulation.

eating approximately every 3 hours, with three meals and two to three snacks: breakfast, morning snack, lunch, afternoon snack, dinner, and possibly an evening snack (if the evening meal is eaten early). It is vital to discuss the benefits of regular eating. These include reducing hunger, which is one cause of binge eating (with reference made to the formulation); raising metabolism; and keeping blood sugar steady (which increases the likelihood of stable mood).

At the start of treatment we do not expect people of low weight to begin eating more food immediately, but early on we encourage all patients to alter their eating pattern, in particular, to spread out more evenly the food they are already consuming.

In her initial self-monitoring forms, Marie's entries showed that she tended to start her food intake at midday, when she ate a small can of tuna and some salad. She then waited until the evening, when she ate a fat-free yogurt and a banana. At this point she was not asked to increase what she ate but was encouraged to shift the content of her food intake to the following pattern:

7 am	½ fat-free yogurt
10 am	½ banana
1 pm	½ can tuna and salad
3:30 pm	½ banana
6 pm	½ can tuna and salad
8:30 pm	½ fat-free yogurt

It should be emphasized to the patient that there is no additional food in this new eating pattern, only a shift in the division of energy consumed throughout the day. Once this new pattern is established, the patient can be encouraged to increase portion size and/or add new ingredients.

Patients often need guidance with meal planning, and many find it helpful to plan their food intake for the entire day, either the previous night or in the morning. They should be told to eat "by the clock" initially, as their hunger and satiety mechanisms will probably have been disrupted as a result of their disordered eating. They need to prioritize eating regularly and should pursue this pattern, even if friends and family are not eating at the same times. They will need reminding that in order to overcome their eating disorder, they need to

view their food as medicine and need to commit to a regular eating plan. They will also need reminding that a bloating sensation is part of the starvation syndrome and does not indicate that they have overeaten. Later in treatment they will need to learn to tolerate normal sensation of fullness, which does not indicate that they have overeaten.

Psychoeducation

Learning more about eating disorders allows patients to increase their motivation to change. All patients receive psychoeducation about the starvation syndrome and its role in their particular eating disorder and information regarding normal eating and balanced nutritional input. They receive information relating to the long-term, irreversible effects of being underweight (e.g., osteoporosis) and of purging (e.g., dental decay). They also learn about the medical dangers of starving and purging (e.g., cardiac arrest). Useful resources for both patients and therapists include chapters 1, 4, and 5 of *Overcoming Binge Eating* (Fairburn, 1995) and the Web site of the Centre for Clinical Interventions (<http://www.cci.health.wa.gov.au>).

If patients are purging, we teach them about the relative ineffectiveness of purging. Laxatives only rid the body of approximately 10% of calories, because these work on the lower bowel, by which time most of the calories in food have been absorbed. Vomiting only rids the body of 30%–50% of calories, because absorption begins in the mouth and by the time they vomit (even if it occurs "immediately"), there has already been significant absorption, especially of carbohydrates, which get absorbed quickly.

Involvement of Significant Others

It is often useful to invite family members or significant others to some sessions. In CBT-E with adults, these sessions are considered not family therapy but adjunct sessions in addition to the regular treatment and are not counted in the total number of planned therapy sessions. It is a good idea to invite family members if they might play a role in either facilitating positive change at home (e.g., by helping with meal planning) or preventing change (e.g., by commenting negatively about the patient's eating).

When adolescents and young people are living at home, there is greater involvement with the family. Parents need to know about their child's eating disorder and what the treatment entails, and they can be of most assistance if they also receive psychoeducation and

have the formulation explained. They can be instrumental in helping the young person establish a regular eating pattern and introduce avoided foods and can assist by removing scales and excess mirrors. They should be involved throughout the treatment.

Stage 2 (Sessions 8–9)

Stage 2 involves a review of treatment, identifying both progress and barriers to progress. We review the formulation and add to it as necessary, which helps us identify the focus of the remainder of treatment.

Stage 3 (Sessions 10–17 in Shorter Treatment; Sessions 10–36 in Longer Treatment)

The main goal of this stage is to change dysfunctional thinking, while continuing the procedures started in stage 1. The focus is on addressing the core psychopathology of eating disorders: the overvaluation of control over eating, shape, and weight.

Identifying the Extent to Which Self-Evaluation Is Based on Controlling Weight/Shape

Patients need to be introduced to the notion of self-evaluation—that is, the ways in which they judge themselves. They then are helped to identify the various aspects of their lives that contribute to this self-evaluation.

One way for patients to assess the various domains of self-evaluation is to create a list of areas of their lives that contribute to their self-evaluation. Typically this list includes aspects of appearance (usually weight/shape), work, family, and relationships. Patients are asked to rank this list in order of importance and create a pie chart, drawing slices representing the relative importance of each domain. Most people with eating disorders judge themselves largely by their ability to control their eating, weight, and shape, and this results in an unbalanced pie chart dominated by weight and shape. Nonetheless, patients are often shocked when they become aware of the extent of this focus, because it is often incompatible with their true values.

It is helpful to educate patients about the riskiness of having such an unbalanced basis for self-evaluation. Firstly, it is like putting all one's eggs in one basket, which may work well when things are going well in that domain (e.g., when they feel they are doing well control-

ling their weight) but poorly when eating seems out of control. Second, self-evaluation based on weight/shape is always tenuous, because of the inherent difficulties of controlling these aspects, and the lack of an objective standard of success. Most patients will agree that there are always reasons to feel dissatisfied regarding their weight and shape, and few circumstances that lead them to feel positive for more than a fleeting moment.

Pie charts can be used throughout treatment to look at changes over time or to identify how they hope their self-evaluation might look in the future (see Figure 10.3).

The next step is to help patients identify ways of making the pie chart—their life—more balanced. They can achieve this by reducing the importance of weight/shape control (the focus of therapy), by expanding existing areas of self-evaluation (e.g., spending more time with friends), or by identifying new or marginalized domains of self-evaluation. These might include interests they have given up (e.g., college), or activities they have always wanted to try. It is most helpful if the new interests have a social component (e.g., volleyball, volunteering).

Identifying the prominent role of weight and shape in self-evaluation easily leads to identifying further consequences, such as preoccupation with food, eating, shape, and weight. The therapist guides the patient to identify experiences or behaviors that result from this preoccupation, as part of a reformulation to include a broader view of the consequences that accompany the unhelpful beliefs, not just the dietary vicious cycle (see Figure 10.4). This increased self-awareness is a further example of decentering from the eating disorder and allows the patient to see it as a set of behaviors, thoughts, and feelings that can be addressed and changed.

Shape Checking and Avoidance

Overvaluation of controlling weight and shape invariably gives rise to a preoccupation with these issues and the development of behaviors oriented toward managing these goals. An important consequence of this overvaluation is body checking, which refers to ritualized checking of aspects of one's appearance with the accompanying motivation to evaluate shape, weight, and body appearance. One example already addressed in stage 1 is weighing. Another common form of body checking involves inspecting one's appearance in the mirror, performed by many patients several times a day. Like weighing, this repetitious activity reinforces preoccupation and dissatisfaction. Other forms of checking

Figure 10.3 Marie's current self-evaluation and her hopes for 5 years from now.

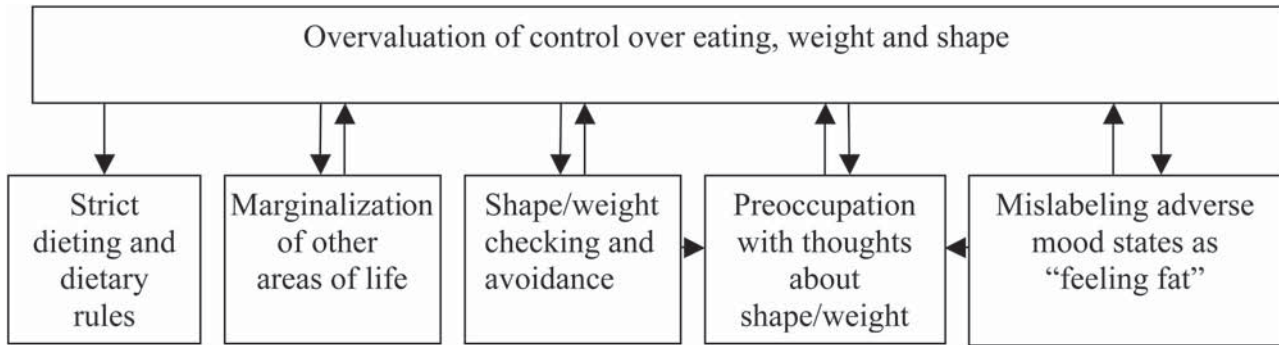

Figure 10.4 Consequences of overvaluation of control over eating, weight, and shape.

include comparison with others (usually those younger and/or thinner, or celebrities), touching parts of the body (especially bones), pinching (to assess “fatness”), using the tightness of clothes as a marker, measuring, and looking down at body parts such as the stomach and thighs. Alternatively, some individuals with eating disorders go to great lengths to avoid seeing their bodies. Avoidance is just as problematic, as it maintains body dissatisfaction by preventing patients from disconfirming their worst fears (e.g., “I have gained 10 pounds”). Furthermore, it is often the cause of much

distress. It interferes socially through avoidance of situations that may involve body exposure (e.g., going to the beach, playing tennis) and in physical intimacy with a partner (e.g., not being seen naked, not wanting to be touched).

Patients need to be given information about body checking. People with eating disorders engage in body checking excessively and often unconsciously, and although it is designed to reassure, it maintains body dissatisfaction. Avoidance is also problematic, as it perpetuates unhelpful fears and beliefs, and needs to

be addressed and suitably managed. First, patients are asked what forms of body checking they engage in. In order to be made aware of their checking behaviors, they are asked to record each act of checking on their self-monitoring sheets, for 1 weekday and 1 day at the weekend. In the next session the therapist and patient go through the records, which often reveal a high extent of body checking that is surprising to patients.

Second, the therapist explores with patients the reasons underlying the checking behaviors. One common reason for checking is “to make sure my body has not got fatter.” Patients need to be reminded about normal body fluctuations (e.g., that a stomach changing shape after a meal is a normal response and is temporary and imperceptible to others) and need help comprehending that a body is unlikely to change much in a short space of time; therefore frequent checking has no value.

Third, the therapist needs to help patients become aware of the negative consequences and perceptual distortions that result from scrutinizing one’s body. Socratic questioning can be useful in helping patients conclude that their frequent checking is not helpful. Patients readily admit that they focus on the parts of their bodies they dislike the most and are not happy after checking their bodies. It is useful to explain that perceptions can be extremely biased. If people look for flaws, they will find some. If a young woman believes she has fat thighs, she will be more likely to perceive her thighs as large—in fact, she may even develop a distorted perception if she continues to scrutinize her thighs, in the way that continued scrutiny of a facial blemish makes the blemish seem to stand out more.

Lastly, the focus is on changing the checking behaviors. There will be some forms of checking that need to be completely extinguished (e.g., using a tape measure to check the circumference of thighs or hips), but most will be addressed through decreasing the frequency and time spent on these behaviors, especially mirror (mis) use and comparison with others.

Mirror use merits detailed examination because it is a typical and frequently employed body checking strategy. It is useful to get a thorough understanding of the ways in which the patient uses mirrors, including the frequency of looking, the length of time spent, the parts of the body scrutinized, whether he or she is clothed or naked, the purpose, and the number of mirrors used. Education about mirrors is particularly important: mirror scrutiny provides misleading information. It is useful to have a full-length mirror available for mirror work. The following exercise challenges people’s belief that their reflection represents an exact image of their body.

Marie was asked to stand far enough away from the mirror that she could see the top of her head and her feet. When asked if she was seeing a full-length reflection of herself that represented her true appearance, she answered, “Yes.” Then the therapist stood by the mirror and asked Marie to identify where on the mirror she could see the top of her head and her feet. The therapist placed a marker those points and measured the distance. Marie was astonished that the reflection was so much shorter than her true height. Her response was, “So what I thought was me was really Mini-Me!”

Once patients see that a reflection is not a true representation of themselves, they are more open to believe in other ways that perceptions can become distorted, and more willing to reduce their mirror scrutiny. The repetitive looking in mirrors also reinforces body dissatisfaction.

Through the discussions about mirrors, Marie became aware that she used mirrors excessively. She looked at herself naked for about 10 minutes when she first got out of bed, then after emptying her bladder, then after breakfast, then after her shower. At work she would go the ladies’ room and if there was nobody there, she would pull up her skirt and examine her thighs in the full-length mirror before and after emptying her bladder. At home she would examine herself naked when she changed out of her work clothes, and again after eating her evening meal. Every time she examined herself, she would end up dejected that she could still see fat on her thighs and that her stomach was not concave. She was shocked to discover, with the help of her therapist, that she was spending an average of 3 hours per day scrutinizing herself in the mirror. Motivated to change, and with help from her therapist, she worked out a plan to reduce her mirror scrutiny.

The other main form of body checking that merits attention is comparisons with others. Like mirror scrutiny, comparing oneself with others most often results in dissatisfaction with one’s body. People with eating disorders are extremely self-critical, but not of others’ bodies.

Furthermore, when they compare themselves with others, they tend to compare themselves with a biased sample of people. They focus mainly on peers or younger individuals who are thin, and celebrities who are thin.

Educating patients about these unrepresentative groups helps them realize the adverse consequences of such comparisons, particularly body dissatisfaction. It is worth pointing out that while their self-scrutiny is biased toward flaws, their examination of others is more focused on positive features. Furthermore, media images of celebrities are likely to have been manipulated. Addressing comparisons with others can involve surveys and behavioral experiments.

After identifying her belief that she had more fat and was less attractive than most other young women of her age, Marie agreed to go to the beach and conduct an experiment. She planned to look at every fifth woman in her age group who walked past her and write down whether she saw any fat on their bodies and how attractive she found them. Her hypothesis was that most women would have no discernible fat and that most would be more attractive than her. She was surprised to find a diversity of body shape and attractiveness.

Avoidance of body shape is best addressed by exposure exercises, where patients are helped to confront their feared experience. They need to get used to seeing and touching their bodies and must cease undressing in the dark and wearing baggy clothes.

Feeling Fat

Many women, especially those in Westernized societies, report the experience of “feeling fat” at certain times, but patients with eating disorders tend to report this as a recurrent and distressing occurrence. They associate this experience, mistakenly, with being fat, and as a result, the experience of feeling fat maintains body dissatisfaction.

Patients need to be educated that feeling fat is not the same as being fat. “Fat” is not an emotion, and the experience is usually triggered by other emotions that are unwelcome or difficult to deal with. Unlike other negative cognitions regarding weight and shape, the state of feeling fat is not constant but often fluctuates with negative moods. Patients are asked to use their monitoring sheets to identify particularly powerful experiences of feeling

fat and the context of such occurrences, in order to identify what other emotions they may have been experiencing at the time. Often patients describe some physical discomfort, such as feeling bloated (which should be addressed through psychoeducation) or negative mood states (which can be addressed by problem solving). The goal is to raise patients’ awareness of the occurrence of feeling fat and to address these experiences in real time by identifying the underlying distress.

Marie often felt fat and was convinced that this was directly related to her gradual weight regain. Through self-monitoring of these experiences of feeling fat, she was able to recognize that the feelings were particularly intense after she spent time with her friend Sally. Sally seemed to be leading the life that Marie wanted. She was doing well at university, she had a boyfriend, and she seemed happy. Once Marie was able to see that what she was really feeling was intense anger and envy of Sally, and guilt for those feelings, she was able to reduce the frequency and intensity of feeling fat as she addressed the underlying emotions.

Identifying the Origins of the Overvaluation

Late in treatment, when patients have worked on reducing the effects of overvaluation of controlling eating weight and shape, it is useful to conduct a historical review in order to identify how the overvaluation developed. Patients are asked to review their childhood up to the onset of the eating disorder in order to identify any predisposing or vulnerability factors (e.g., being overweight, having a mother who was constantly dieting) and the effect that those might have had on their self-evaluation. They are then asked to recall any precipitating factors, or triggers that occurred before their eating disorder (e.g., parents divorcing, a boy telling her he liked skinny girls). The therapist then discusses with the patient the factors that might have maintained the disorder in the first few months (e.g., positive reinforcement for weight loss, a sense of control). Finally, the patient identifies the course of the disorder in the period since its appearance, and any factors that might have influenced its pattern.

This process of examining the past cannot undo the negative experiences of the past, but patients find it

beneficial. It helps them place their eating disorder in the context of their entire life and is a further means of distancing themselves from the disorder. It also prepares them for examining the pervasive set of messages they may have lived with for years: the eating disorder mind-set.

Marie came to understand that she had grown up in an atmosphere of “healthy” eating. When she put on weight at puberty, she developed the belief that there was something wrong with her and that she was to blame for her change in shape. This increased her vulnerability, and when she went on a diet and received compliments, she mistakenly thought that being thin was the only way to be popular and happy. At this point in her life and after several months of therapy, she was able to see that maintaining a precariously low weight had only served to narrow her life choices and had not brought happiness.

The Eating Disorder Mind-Set

An eating disorder mind-set reflects the core psychopathology of eating disorders, namely, the overvaluation of controlling eating, weight, and shape. It affects the way in which individuals filter experience. Just as wearing a pair of pink glasses makes the world appear pink, a mind-set can alter the way someone interprets comments. For example, “You look well” will be interpreted by someone with an eating disorder as “You look fat.” This overarching mind-set leads patients to engage in the behaviors that reinforce it (e.g., food restriction, body checking, and mislabeling negative emotions as “feeling fat”).

The focus of treatment up to this point has been to address and reduce the processes that maintain the eating disorder and its accompanying mind-set. Patients have been developing new, more positive self-statements and reducing their negative messages. At this stage of treatment the focus shifts to learning to control the eating disorder mind-set. It is useful to compare the mind-set with a DVD player and aim to control the playing of the DVDs. Most people have different DVDs relating to different areas of their lives, and they switch easily from one to another (e.g., from friends to work). Unfortunately, the eating disorder mind-set tends to become locked in, repeating old messages that become ingrained. As treatment progresses, these messages tend to fade into the background at times but can reappear suddenly.

Patients will be aware of the times the eating disorder mind-set slips back into place. In order to have more control over this mind-set, they need to learn to identify possible triggers for its recurrence and early warning signs that it is playing, and how to displace it and/or replace it with other healthier messages (i.e., “eject” the DVD).

Marie was pleased because she was finding it easier to eat with her friends. She was no longer bombarded with internal voices telling her, “If you eat what they’re eating, you’re a filthy pig!” However, she reported that she had cancelled a dinner date with friends, as she kept hearing inside her head, “You’re a fat pig, you should eat less!” A review of the previous couple of days before this recent setback revealed that she had been distressed that she needed a larger size of jeans. With her therapist’s help, she was able to link this discovery with the re-playing of the old “DVD” and became more aware of possible triggers (shape concerns) and early warning signs (self-denigration and restricting). The next time she had a negative experience with her shape (comparing herself with an emaciated young girl) and she became aware of her impulse to restrict, she was able to reinstate a healthier eating pattern.

Dietary Restraint and Dietary Rules

While dietary restraint is addressed in stage 1 in the context of the formulation, regular eating, and psychoeducation, it needs to be revisited in stage 3. An early focus is on helping patients understand that, contrary to their belief that dieting is the answer, dietary restraint is problematic for them.

Most people with eating disorders are reluctant to give up dieting altogether, especially if they have had success with weight loss, because they have attributed their loss (and maintenance) to dieting. Those who binge tend to use dieting as a major compensatory behavior. For many individuals with eating disorders, especially those of low weight, dieting is something that gives them a sense of achievement and of being in control. Even when they sense they are failing, they blame themselves rather than recognize the unreasonable goals they have set for themselves.

Patients need to be reminded of the role that dieting plays in binge eating (or the likelihood of such), and in their preoccupation with controlling their eating, shape, and weight. Most patients have developed extremely rigid dietary rules, and one major problem with dietary rules

is that they tend to be inflexible and difficult to maintain. A common response is anxiety, especially when a rule is broken, if only slightly. Patients think, “I’ve blown it!” and this is often followed by guilt, feelings of failure, and/or binge eating, and then resumption of the dieting. This dichotomous thinking can be addressed by typical CBT techniques such as thought diaries.

Having inflexible rules also restricts social interaction, as eating out (i.e., eating foods of unknown composition) becomes intolerable, and eating with others becomes associated with fears of being thought weak and/or greedy.

Although there are many idiosyncratic sets of dietary rules, there are three common forms:

- When to eat (e.g., never before noon, never after 7 pm, only twice per day)
- What to eat (e.g., no white bread, only one portion of carbohydrates per day)
- How much to eat (e.g., portion size, caloric limit)

The first rule will have been addressed in stage 1 through regular eating. The second is best addressed as food avoidance and tackled as a set of behavioral experiments.

Marie was asked to identify all her avoided foods by visiting every aisle of the supermarket and listing all the foods she avoided for fear of weight gain or fear of triggering a binge. When she got home she divided the foods into 4 groups (see Exhibit 10.3).

She agreed to try 2 items from the first column and to note these efforts on her self-monitoring record. She chose low-fat cheese and whole-wheat

bread and was able to eat both on 2 occasions during the next week when she felt in control of her eating. Her weight only changed by 150 grams. She felt relieved, as she realized that she didn’t need to eat a cheese sandwich every day, but she knew she could when out with friends.

Foods should be systematically reintroduced, even in small quantities, until patients’ dietary rules have become more flexible and the foods no longer cause anxiety. Only small amounts need to be tried, because eating even small amounts means the dietary rule has been broken. Like many aspects of eating disorders, dieting and dietary rules are most successfully addressed when the patient wants to change. Patients should be helped to understand the negative and limiting impact of strict dieting—on their social lives and their mood states—and encouraged to experiment with relaxing their dietary rules. The third typical food rule (amount) is best addressed in the context of nutritional education and the goal of consuming balanced meals and maintaining a stable healthy weight. Recommendations concerning portion size will depend on the nutritional needs of the patient, and a dietitian can play an extremely important role in this task.

The Impact of Moods and Events on Eating

Moods have an impact on most people’s eating, with some individuals falling at one end of the spectrum, where moods play a minor role, and others falling at the far end, where adverse mood states are barely tolerated and have a significant impact on eating behaviors. Restriction and exercise tend to occur in response to events that make the individual feel out of control,

10.3 | Avoided Foods

I might just consider eating	Maybe one day (not now), I could eat	Really hard to eat	I can’t imagine eating these!
Whole-wheat bread	Muesli	White bread	Butter
Low-fat yogurt	Avocado	Potato chips (pack)	Ice cream
Corn	Potatoes	Sugar in tea	Cream
Low-fat cheese	Whole-wheat pasta	Full-fat yogurt	French fries
Tomato ketchup	Honey	Pasta (regular)	Fried chicken
Dried apricots	Muesli bar	Chocolate bar	Full-fat cheeses
	Raisins	Cake	Pizza

while binge eating and purging are often efforts to cope with negative moods and/or events.

Although some patients want to address their moods early in treatment, this is not helpful until the other factors maintaining binge eating (e.g., dietary restraint) have weakened, and individuals are only experiencing residual binges. As with most interventions, the first task is for patients to become aware of the link between events, moods, and eating, with information coming from self-monitoring records.

Event-related changes in eating are addressed through the 7 steps of structured problem solving. The strategy of binge analysis can be used to address residual binges. Breaking a binge into steps is often useful in that it introduces the notion that a binge is not inevitable. The therapist helps the patient identify the trigger, which is usually dieting or breaking a dietary rule, disinhibition from alcohol/drugs, or moods/events. By retracing the events that lead up to the binge, patients can identify what else they could have done—and what strategies they could use in the future. This is surprisingly novel to many patients and gives them a sense of control over their eating and their lives.

The presence of severe mood intolerance will have been identified in stage 2 and is often seen in patients who continue binge eating despite regular eating. The binge and/or purge behaviors often coexist with other attempts to regulate moods, such as self-harm (cutting, scratching) and self-medication (with drugs, alcohol). Difficulty tolerating moods needs to be addressed in detail. Patients learn the typical chain of events: a triggering event (e.g., meeting up with a university friend), a negative appraisal of that event (e.g., “I’m not as good as she is”), an adverse mood (e.g., anger, envy), and a negative appraisal and escalation of that mood change (e.g., “I hate feeling envious, I hate it, I hate it!”). This is followed by unhelpful mood-modulating behaviors (e.g., binge eating) and an immediate reduction in the emotion, but with a self-blaming response (e.g., “I am a hopeless failure and I hate myself”).

Marie was taught to identify, in the moment, a triggering event, and write down what happened, her understanding of what happened, her current emotion, and her appraisal of this emotion. This gave her some control over her responses and interrupted the escalation of emotion. She was taught to intervene at different stages. Problem solving was particularly useful for dealing with triggering events. Cognitive interventions such as thought

diaries were helpful for addressing the negative appraisal of such events. Mindfulness (sitting with the emotion and observing in a nonjudgmental way) was useful for dealing with adverse moods and their negative appraisal. For unhelpful mood-modulating behaviors, she engaged in activities that were distracting (calling or meeting a friend, listening to music, going for a short walk) or self-soothing (having a shower or bath).

Although these new behaviors will not give the immediate relief obtained from binge eating or self-harming, they offer an alternative response to what was previously thought of as an inevitable chain of events. It is another example of patients gaining more control over their lives as they gain awareness of the possibility of healthier options.

Stage 4 (Sessions 18–20 in the Short Treatment; 37–40 in the Long Treatment)

It is important for treatment to end in a planned way. These final sessions occur at fortnightly intervals, with the emphasis on patients continuing to practice their skills in the future. There is an expectation that improvement will continue. Self-monitoring is phased out, and in-session weighing is replaced with at-home weekly weighing.

Maintaining Progress

The therapist and patient assess progress and identify what has been most useful in treatment, so that the patient can continue to use those strategies or techniques. They identify areas that remain problematic and create a plan for how the patient will continue to work on those areas.

Relapse Prevention

It is important for patients to have realistic expectations. The eating disorder mind-set may always be an Achilles’ heel, and they may be prone to resuming old patterns of coping in response to certain triggers. However, they are encouraged to recall the skills that they have acquired to influence the old mind-set, and to continue to use them. Patients need to distinguish between a lapse and a relapse, seeing the former as a

temporary setback from which they can get back on track immediately.

Patients need to be helped to identify likely triggers for setbacks. The therapist helps them create a plan to deal with setbacks.

Emotional Intelligence and Substance Abuse: An Integrative Approach to Assessment and Treatment

Denise Fortino

The aim of this chapter is to investigate the phenomenon of chemical dependence from a personality-centered perspective to help clinicians understand the factors that are associated with resistance as well as susceptibility to addictive drug use. Rather than dwelling almost exclusively on the pathological aspects of addiction, as has been traditional, this chapter will explore personality dimensions that may be conducive to healing and recovery. Both clinicians and researchers in the field of addiction treatment have noted that many substance abuse counselors often appear to rely on moral/criminal- and disease-based models that center more on *DSM-IV* labeling and the rigid stereotyping of clients than on considerations of their inherent strengths or unrealized potentials. Even in relatively enlightened settings there may be an undercurrent, often only thinly disguised, of pejorative and unchallenged assumptions—that the chemically dependent as a whole are not only profoundly defective, but also weak willed and lacking in discipline, relentlessly manipulative, generally untrustworthy or outright deceitful, best managed through confrontational approaches, and ultimately incapable of significant change.

Such a pessimistic, skeptical view seemingly offers little room for lasting hope or fundamentally positive regard for those in treatment. One patient confided during an intake interview that he had hesitated to tell a psychiatrist who was treating him for depression that he was in a methadone program until he summoned up the courage after about a year in her care. Unfortunately, he found that her attitude toward him changed so dramatically thereafter—beginning with her statement that he had behaved with an appalling degree of dishonesty and deception—that he eventually stopped his visits. Ironically, his initial hesitation seemed justified in retrospect, given her negative reaction to his disclosure.

A similarly judgmental and one-dimensional depiction of addicted individuals was evident in the report of a research study comparing the relatively successful performance of heroin-using Vietnam veterans on the Halstead-Reitan battery with that of a control group some 30 years ago (Fields & Fullerton, 1975). The addicted group outperformed the controls on eight of the nine subtests with one, a test of abstract reasoning, approaching statistical significance. The investigators

speculated that the higher conceptual ability demonstrated by the addicted group “may well account for the manner in which many addicted persons are able to *manipulate others to do their bidding*” (p. 114, italics added). Moreover, they concluded that two courses of action were available to the heroin-dependent veteran with regard to this purported superiority: “He might be helped to use these facilities in a constructive/rehabilitative manner or he might *continue to use them to manipulate others* in what ultimately becomes a self-destructive cause” (p. 114; italics added). Such descriptions of the “manipulative” heroin-addicted individual seem to have been part of a widespread perception that may well have influenced the kinds of interventions traditionally aimed at this group.

When Rudolph Moos, a researcher well known for his studies on adaptive coping in alcoholics, decided to investigate why some people improve and recover, he was dismayed to learn that an emphasis on positive outcomes was not considered a worthy enterprise by his colleagues, who regarded recovery itself as a rather insubstantial, ephemeral concept. The conventional wisdom of the time cast doubt on the ability of anyone to genuinely overcome a history of alcohol dependence or the emotional consequences of any similarly severe long-term illness (Moos, 1994). This outlook synchronized with the more crudely phrased idea “Once a junkie, always a junkie.” Sadly, this is how many drug users have come to see and define themselves and, as already observed, the professionals who treat them are not necessarily immune from such dismissive and simplistic views. Indeed, no other population of clients appears to have been more maligned and misunderstood than individuals who are addicted to drugs or alcohol (Miller & Brown, 1997).

Aside from political pressures and culturally ingrained prejudices, one problem with the treatment of addiction may be that the field has been marked by a shortage of humanistically oriented psychologists who possess the requisite skills to handle the problems of substance-dependent clients with the compassion and complexity they deserve (Miller & Brown, 1997). Those who seek help are too often subjected to one-size-fits-all kinds of treatments, as if they had identical profiles. In part, this chapter represents an effort to demonstrate that this is definitely not the case—and that people may become chemically dependent for widely varying reasons, with distinctive ways of perceiving, processing, and responding to emotional distress.

To be sure, many, if not most, of the clients in treatment for addictive drug use present with deep-seated vulnerabilities, but often these do not seem to be ei-

ther adequately explained or differentiated, and whatever strengths they might possess, such as a readiness for interpersonal engagement, imaginative capacity, creativity, introspection, empathy, affective intensity, beneficial attentional shifts, and/or potential for self-soothing, may be largely overlooked. Fortunately, one recent development has been an effort by agencies that accredit substance abuse treatment programs to reconceptualize clients in terms of their strengths and abilities rather than viewing them from a predominantly pathological perspective.

As for finding more authentic ways of identifying what indeed may be defective as well as healthy and adaptive in these individuals, it has been observed that while many of the clients seen in treatment are exceptionally sensitive, verbal, and creative, at times they also seem profoundly uneasy, if not altogether blindsided, with regard to understanding and giving voice to both their own and others’ range of feelings. Accordingly, it may be beneficial to focus on exploring the cognitions and perceptions that are at the heart of this not always well-articulated and well-managed emotionality. Moreover, it is reasonable to propose that such difficulties with affective expression and regulation not only have rendered many of these men and women susceptible to a substance use disorder in the first place, but over time might also be remediable through interventions that take such proclivities into account.

Toward this end, this chapter offers a clinically relevant way of understanding the phenomenon of substance use that focuses on clients’ capacities for healing and wellness in addition to their disabilities, and that highlights rather than obscures their individual differences. At the basis of this perspective are two conceptual models that seem especially relevant to this population: the construct of emotional intelligence as developed by Salovey and Mayer (1989–1990) and the high-risk model of threat perception (Wickramasekera, 1988, 1995), a multidimensional theory specifying the cognitive, affective, and psychosocial factors that can amplify or attenuate the perception of threat at the basis of many psychological and somatic disorders. The personality dimensions of alexithymia, negative affect, absorption, private self-consciousness, and repressive coping that have been derived and adapted from these models are associated with the capacity to comprehend, communicate, and modulate emotion (Fenigstein, 1997; Roche & McConkey, 1990; Taylor, Bagby, & Parker, 1997; Weinberger, Schwartz, & Davidson, 1979; Wickramasekera, 1995). Both individually and collectively, these five variables may influence attentional and cognitive processes as well as physiological reactivity, which in

turn can have an impact on how we perceive, express, and regulate our emotional states.

In a recent study of heroin users, these personal-ity variables were explored both singly and in concert as significant risk or protective factors with regard to maintaining abstinence from drug use and successfully managing interpersonal relationships in both intimate family and broader social settings (Fortino, 2002). The primary clinical utility of such a model lies in its potential as a descriptive and multidimensional tool that can help identify clients' strengths as well as limitations in more individualized, affectively nuanced ways and determine areas of focus for interventions that can enhance both their responsiveness to and eventual outcomes in treatment.

EMOTIONAL INTELLIGENCE, AFFECT REGULATION, AND SUBSTANCE USE

As already noted, one popular and persistent image of the chemically dependent is that they are quite adept at manipulating people for the sake of their addiction—and thus, by implication, are possessed of at least some degree of emotional and social sophistication, or intelligence. However, a closer look at many such individuals often reveals a pervasively low tolerance for emotional distress, a relative lack of insight in relation to both self and others, impulsivity, poor judgment, and a paucity of resources for coping with even the most trivial frustrations or setbacks—seemingly the very essence of emotionally *unintelligent* behavior. Indeed, while much of this behavior may be the direct and painful consequence of the addiction itself, it is also possible that these individuals' relative difficulty in appraising, expressing, and managing their own emotional states along with those of others placed them at risk for a substance use disorder to begin with (Bell & Khantzian, 1991; Giannini, 1996; Khantzian, 1982, 1990, 1993; Krystal & Raskin, 1970; Lynch, 1985; Mann, Wise, Trinidad, & Kohanski, 1995; Rybakowski, Ziolkowski, Zasadzka, & Brzezinski, 1988; Taylor et al., 1997; Taylor, Parker, & Bagby, 1990; Wursmer, 1974; Ziolkowski, Gruss, & Rybakowski, 1995).

Although problems with affect regulation assume varying and sometimes even notably contrasting forms in different individuals, all may denote maladaptations in the cognitive processing of emotion and may heighten susceptibility to addictive behavior (Taylor et al., 1997). Viewing chemical dependency from the perspective of affect regulation, emotional intelligence, and cognitive style may have important clinical implications for indi-

vidualizing treatments, preventing relapse, and enhancing or redirecting existing strengths and skills. Thus, it might be possible to predict that individuals with certain constellations of the personality dimensions that are related to emotional intelligence will have greater difficulty or success in treatment than those with a different grouping of such factors. When these personality factors are considered within the context of social supports and particular coping or interpersonal problem-solving skills, it may be possible to identify what contributes to the long-term success of individuals or places them at ongoing risk for relapse in treatment settings.

Although abstinence from illicit drug use is one important and obvious criterion for a favorable outcome in treatment, the ability to manage emotional and interpersonal problems is also of immediate relevance to the treatment success of heroin-dependent individuals, a significant number of whom may relapse because of difficulties in this domain. Indeed, the ability to cultivate, sustain, and benefit from supportive interpersonal relationships is a skill that may be critical to recovery from a substance use disorder (Appel & Kaestner, 1979; Doumas, Blasey, & Dicks, 1999). While studies have examined associations between social competence and/or coping skills and risks for addictive drug use (e.g., Doumas et al., 1999; Matthews & Wells, 1996; Pentz, 1985; Wills & Hirky, 1996; Wills & Shiffman, 1985), few have examined direct relationships between a global capacity for affect regulation or emotional intelligence in connection with both self and others and the performance of substance-dependent individuals in treatment programs. Moreover, empirical research on the roles of imaginal capacity, introspection, attentiveness, creativity, and self-soothing in the context of potential recovery from addictive behavior has been scant. Varying levels of such attributes may help explain both vulnerability and resistance to chemical dependence and also determine the kinds of interventions that may be optimally effective for different individuals.

According to the researchers who first defined this construct, *emotional intelligence* refers to the ability to monitor one's and others' emotions, discriminate among them, and use this information effectively to guide both thinking and behavior (Salovey & Mayer, 1989–1990). Broad in scope, this capacity encompasses the verbal and nonverbal appraisal and expression of emotion, the perception and regulation of mood states in oneself and others, and the ability to process and adapt to affective information for everyday problem solving, a skill that involves flexibility, creative thinking, and redirected attention (Mayer & Salovey, 1993; Schutte, Malouff, Hall, Haggerty, Cooper, Golden, & Dornheim, 1998). Given

this definition, difficulties involving the appraisal of emotion in self and others might be reconceptualized as specific skills deficits that may be identified, assessed, and remedied through appropriate interventions (Mayer, DiPaolo, & Salovey, 1990).

Wickramasekera (1995) identified three key components rendering people more susceptible to perceptions of threat—predisposers, triggers, and buffers—that can culminate in significant psychological and somatic symptoms. In his model, the internal predisposers are the personality variables of high or low hypnotic ability; high neuroticism, or negative affect; and high or low repressive coping. Together, these factors can increase the likelihood that major life changes or minor daily hassles will produce psychological or physical distress unless they are buffered by positive social support and more appropriate forms of coping or self-enhancement (Wickramasekera, 1995). The quantifiable components of Wickramasekera's multidimensional model may be relatively weak predictors of clinical outcomes when considered separately but in concert are often robust representations of the complex mind-body interactions observed in real clinical situations (Wickramasekera, 1988, 1995).

A stable individual difference variable, hypnotic ability is a psychophysiological condition of altered attention as well as reduction of both peripheral awareness and critical/analytic thinking; the result can be major changes in perception, mood, and memory that are sufficient to produce significant biological and behavioral effects (Wickramasekera, 1988, 1995). This visual and uncritical/emotional mode of information processing occurs typically during periods of high or low physiological arousal and may be viewed as a trait-like ability, not a transitory state prompted simply by hypnotic inductions (Wickramasekera, 1988).

Highly hypnotizable people can generate rich and vivid images of sensory experience and engage in affectively charged fantasy activity; those who are also high in negative affect tend to amplify even minor or neutral phenomena to a level of self-perceived significance, with the potential for both psychological and somatic consequences (Wickramasekera, 1995). Those who are low in hypnotic ability are relatively unaware of psychological threats, tend to deny the role of psychological variables in their physical symptoms, are not apt to verbalize negative feelings when under stress, and attenuate the perception of threat by developing somatic symptoms (Wickramasekera, 1995).

Neuroticism, or negative affect, which denotes a tendency to recognize as well as recall predominantly aversive events and memories, is considered to be

stable across time and independent of objective stress. Based on autonomic lability, or degree of reactivity of the sympathetic nervous system, neuroticism appears to have a genetic basis (Eysenck, 1960; Shields, 1962). People who are high in neuroticism are hypersensitive to threat, have an attentional bias toward threat in information processing, and show an enhanced implicit or explicit memory for distressing events (Wickramasekera, 1995).

Those identified as defensive or repressive copers show discrepancies between verbal reports and objective physiological measures of distress and selectively attend to positive stimuli (Lane, Merikangas, Schwartz, Huang, & Prusoff, 1990; Weinberger et al., 1979). One price of such repressive self-regulation and apparent emotional equanimity may be somatic illness, while too little repressive coping may increase vulnerability to psychopathology (Weinberger et al., 1979).

This chapter will discuss five personality factors that reflect some features of Wickramasekera's multidimensional model while modifying and adding others. Based on previous research with populations of substance users, the two personality dimensions of alexithymia and self-consciousness, which have relevance to the affect-regulating aspects of chemical addiction, are included here for consideration. Moreover, instead of hypnotic ability, absorption, which has been studied primarily as a personality correlate of hypnotic ability and is related to the "openness to experience" dimension of the five-factor model of personality (McCrae & Costa, 1987), is presented as a variable in its own right with significant implications for heightened emotional well-being (or distress). Some individuals who are high in absorption can draw upon capacities for affective engagement, potentially beneficial attentional shifts, fantasy, creative pursuits, spirituality, and empathically altered states of consciousness (Levin, Wickramasekera, & Hirshberg, 1998). Such tendencies are potentially effective means of coping that may be relevant to recovery from addictive drug use and similar disorders. The personality variable of alexithymia is reviewed and presented first because this construct has been explored most extensively in the context of disorders of affect management, including substance dependence, and forms an important counterpoint to the other personality dimensions investigated in this chapter.¹

1. Substance abuse and dependence are considered distinct diagnoses in the *DSM-IV*, although some researchers view any demarcation between these terms as rather arbitrary because abuse may be simply a milder form of dependence. This author chose dependence as the primary nomenclature in this chapter.

ALEXITHYMIA

Clinicians have long observed that a significant number of clients have difficulty articulating their emotional states, finding it hard literally to put their feelings into words or to distinguish them from—as well as relate them to—their concurrent bodily sensations. These individuals are either largely unaware of their emotions and moods or else able to describe them only in vague, detached, and superficial ways. They also show a conspicuous incapacity for fantasy, introspection, and symbolic dreams and often appear preoccupied with the concrete, mundane details of external events (Lesser, 1981; Nemiah, Freyberger, & Sifneos, 1976; Taylor, 1984). Moreover, such individuals are also known to lack empathic ability and have difficulty recognizing specific emotional states in others (Giannini, 1996).

This apparent absence of emotional literacy, as it were, has been labeled *alexithymia* (literally, “without words for feelings”), an affective and cognitive style that has been observed commonly in those with chronic somatic complaints, eating disorders, chemical dependency, post-traumatic stress disorder, and a number of other medical and psychiatric conditions (Cohen, Auld, & Brooker, 1994; Finn, Martin, & Pihl, 1987; Haviland, Hendryx, Cummings, Shaw, & MacMurray, 1991; Krystal, 1979; Lesser, 1981; Nemiah et al., 1976). Rather than being conceptualized categorically as an all-or-none phenomenon, alexithymia should be viewed dimensionally as a personality trait occurring along a continuum (Taylor, 1984). As Swiller (1988) observes, not everyone has this “communicative style” to the same extent, and in “small amounts” it might be quite prevalent (p. 48).

It has also been noted that alexithymia may represent a transient albeit potentially enduring state rather than a stable and continuous characteristic, as it is often an adaptive response to severe ongoing physical or emotional stress, or previous trauma (Haviland, Shaw, Cummings, & MacMurray, 1988; Krystal, Giller, & Cicchetti, 1986; Wise, Mann, Mitchell, Hryvniak, & Hill, 1990). For example, Freyberger (1977) observed constricted affective responsiveness and reduced imaginal activity in some seriously ill patients undergoing medically stressful procedures, such as hemodialysis, organ transplantation, and intensive care; those whose diseases become chronic may not experience a diminution in alexithymic features. Krystal (1988) cited the prevalence of “secondary” or situational alexithymia in survivors of Nazi concentration camps. Whether the trauma originates in early infant development or occurs later

in life may determine how entrenched the alexithymic behavior ultimately becomes in certain individuals and how responsive it is to psychotherapeutic intervention (Krystal, 1988) as well as how prominent a role it can play in susceptibility to particular conditions such as substance dependence and subsequent relapse.

It should be noted that individuals vary widely in the severity and consistency of their alexithymic characteristics, and that most with such predominant traits can experience significant feelings some of the time (Krystal, 1979). Outwardly, some people identified as alexithymic who are also drug-dependent may appear to contradict this personality type because they display chronic dysphoria or intense, short-lived outbursts of emotional behavior such as crying or rage reactions (Krystal, 1979). However, clinical investigation suggests that they remain essentially unaware of the underlying feelings thereby expressed and, in most cases, are unable to connect their distress with memories, mental images, higher-order affects, or particular situations (Krystal, 1979; Taylor et al., 1997). Sometimes the emotional eruptions end as quickly as they begin and come across more as a performance than an authentic expression of feeling (Krystal, 1979). When asked to elaborate on complaints of anxiety or depression, such individuals are apt to resort to impersonal, attenuated, and trivialized descriptions; thus, their anxiety may be referred to as “nervousness, agitation, restlessness, irritability and tension,” while their depression may be labeled “emptiness, void, boredom and pain” (Sifneos, as cited in Taylor et al., 1997, p. 29).

As Goleman (1995) observes, it is not that alexithymics never feel, but rather that they are lacking in the fundamental skills of emotional intelligence, one crucial aspect of which is self-awareness. Generally confounded by their distress, they may feel “awful” after watching a sad movie but not be able to identify exactly what *kind* of awful it is. Thus, although alexithymic individuals can report episodes of emotional disturbance, they may be relatively lacking in the reflective self-understanding to make appropriate connections regarding the origin or significance of these feelings. Such a chasm between verbal and emotional expression means that while words such as “love,” “hate,” “anger,” and “ecstasy” are used by alexithymics, they may infer only a pseudo understanding of feeling; the result can be a glib display of emotional colorblindness that readily eludes detection (Lynch, 1985).

Moreover, in a social context alexithymic individuals frequently, albeit unwittingly, use language not to communicate openly with others, but rather to conceal and deflect their feelings. Instead of serving as an

invitation for others to enter their world and bridge the distance between them, their speech may become a way of insulating themselves from meaningful interpersonal contact (Lynch, 1985).

Not having a self-revealing, richly elaborated way to comprehend or communicate emotions through the medium of language may render such people particularly vulnerable to physical and behavioral dysfunction. Without an adequate means of conveying feelings symbolically, the only remaining outlet for those who are introspectively limited and externally engaged may be the body itself, which heightens the risk of a breakdown in some organ system, or poorly regulated behavior (Krystal, 1979; Lesser, 1981; Wickramasekera, 1988). When experiencing distressing affects, some alexithymic individuals may amplify normal somatic sensations and cognitively imbue them with aversive meanings; others may be unaware of their own bodily reactions altogether and are likely to be the kinds of individuals who delay seeking both medical and psychological help (Lynch, 1985; Wickramasekera, 1988). Still others may resort to physical action as an immediate response to and means of coping with undesirable feelings (Bagby, Taylor, & Atkinson, 1988; Taylor, Bagby, & Parker, 1991, 1997).

Besides the tendency toward hypochondriasis observed in many alexithymics (Bagby, Taylor, & Ryan, 1986), prolonged, poorly regulated states of emotional stimulation may result in exacerbated responses in the neuroendocrine and autonomic nervous systems, setting the stage for the development of specific somatic imbalances or illnesses (Taylor et al., 1997). Berry and Pennebaker (1993) observe that the verbal expression of emotional distress—the capacity considered to be lacking in alexithymics—can possibly reduce this covert autonomic arousal and its related physiological consequences.

To determine whether alexithymia represents a purely linguistic phenomenon (Lane, Sechrest, Reidel, Brown, Kaszniak, & Schwartz, 1995), researchers compared performances on both the verbal and nonverbal identification of emotion in 384 individuals with no prior psychiatric history, 51 of whom were rated alexithymic by the original 26-item Toronto Alexithymia Scale (TAS), which is considered a valid and reliable self-report measure of this construct. The alexithymics scored significantly lower than other subjects on both the verbal and visual wordless tasks, which involved the ability to identify and match emotional stimuli in faces and photographs. The results suggest that the essential feature of alexithymia—a difficulty articulating feelings—represents a more *general* deficit in the capac-

ity for processing emotional information (Lane et al., 1995).

Some researchers have also questioned whether alexithymia is merely a social or cultural artifact reflecting national or class differences in the expression or display of emotion and the conduct of interpersonal relationships rather than a universal psychological entity (Borens, Gross-Schulte, Joensch, & Kortemme, 1977; Prince, 1987.) However, the successful cross-validation of both the original 26-item self-report Toronto Alexithymia Scale (TAS-26) and the most recent 20-item revision of the scale (TAS-20) in many different countries, including Japan, India, Italy, Finland, and Korea, as well as clinical reports of alexithymia in diverse cultures in both normal and clinical populations (Taylor et al., 1997), appear to be compelling arguments against this proposition.

Alexithymia and Negative Affect

If alexithymia reflects difficulties in both the cognitive processing and regulation of emotional states (Krystal, 1990; Lane & Schwartz, 1987; Taylor et al., 1997), one would also expect people with this characteristic to manifest recurring emotional distress, albeit in a covert and thinly verbalized way, or in the form of not-well-understood and poorly integrated temperamental outbursts. Indeed, such unpleasant feelings may become global, threatening, and even overwhelming for these individuals precisely because of their limited capacity to differentiate and modulate emotional states (Taylor et al., 1997). Thus, besides generating bodily complaints, dysregulation or heightened activation of the autonomic nervous system is associated with a proneness to persistently dysphoric moods, a disposition that corresponds with the trait of neuroticism, or negative affect (Taylor et al., 1997; Watson & Clark, 1984).

As distinguished from alexithymia, neuroticism is a personality trait that has been described as a global disposition to experience aversive emotional states—anger, guilt, self-dissatisfaction, rejection, sadness, and worry, among others—even in the absence of overt environmental stressors (Wickramasekera, 1988). Costa and McCrae (1987) defined neuroticism as a “broad dimension of individual differences in the tendency to experience negative, distressing emotions and to possess associated behavioral and cognitive traits” (p. 301). Watson and Clark (1984) maintain that negative affect correlates so strongly with Eysenck’s concept of neuroticism that they can be viewed as measuring the same construct. There is considerable evidence that neuroti-

cism is quite stable (McCrae & Costa, 1987) as well as heritable (Tellegen, Lykken, Bouchard, Wilcox, Segal, & Rich, 1988).

Neurophysiological studies have markedly associated negative affect and neuroticism with activation of the right cerebral hemisphere (Davidson, 1984; Tomarken, Davidson, Wheeler, & Doss, 1992). Eysenck's own earlier theory of personality structure encompassed a general activity factor labeled E-I (extraversion-introversion) and an emotionality factor designated neuroticism (N), each of which corresponds to specific cortical and subcortical centers of the brain. Central to the theory is the construct of general arousal, a pervasive activation of the body's major response systems observable through physiological measures such as skin conductance, cortical arousal, and cardiovascular activity (Geen, 1997).

Varying levels of neuroticism and extraversion may be related to individual differences in brain stem arousal as well as the reactivity of the autonomic nervous system to sensory stimulation. As a result of the lability associated with high neuroticism, affective dysregulation resulting from stress may be prolonged in individuals with a high-N profile (Eysenck, 1990). Besides involving the measurement of E, I, and N through the rigorously developed and validated Eysenck Personality Inventory, Eysenck's theory generates predictions of experiential and behavioral distinctions that are related to the psychophysiological differences along the E-I and N dimensions and to each other (Geen, 1997).

A major criticism of the concept of general arousal has been that indicators of such activity in the various cortical, motor, and autonomic systems often show weak intercorrelations at best and are also not robustly connected to behavioral outcomes. While there has been relatively strong evidence of E-I differences in studies of evoked responses, or momentary changes in brain-wave activity that occur in response to brief presentations of a stimulus, studies assigned to test associations between physiological processes and neuroticism have not yielded either consistent or impressive results (Geen, 1997).

One possible explanation for this is that significant differences in autonomic activation or somatic responsiveness between high and low neuroticism scorers will occur only under relatively stressful or anxiety-arousing conditions that cannot realistically be reproduced in laboratory settings given the obvious limits sets by ethical considerations (Eysenck & Eysenck, 1985; Geen, 1997). Thus, the psychophysiological data collected thus far may simply not be "sufficiently detailed or sensitive to permit precise identification of the underlying physi-

ological structures" (Eysenck & Eysenck, 1985, p. 235). Another possibility for the inconsistent results in high-N subjects is that varying levels of extraversion may not be considered as a factor that could influence the outcome in these cases (Canli, Zhao, Desmond, Kang, Gross, & Gabrieli, 2001).

Supporting earlier brain research, a recent study of individuals previously identified as either extraverted or high in neuroticism through the NEO Personality Inventory used magnetic resonance imaging technology to measure their responses to strongly negative and positive images. Individuals who scored high on neuroticism were found to have more reactivity to negative stimuli in several areas of the brain that regulate emotion, including the amygdala, than those who were high in extraversion. This suggests that individual differences in brain reactivity to potent emotional stimuli may be associated with specific personality traits, and that differences in levels of extraversion among those rated as high in neuroticism may account for inconsistencies in their physiological profiles, as noted above (Canli et al., 2001).

Whatever the limitations associated with their measurement, the relevance of neurophysiological factors to the study of personality in general or Eysenck's theory in particular remains compelling (Geen, 1997). Moreover, individual differences in coping styles and in personal beliefs regarding the ability to deal with problems may themselves be correlated with specific patterns of physiological activity (Bandura, Cioffi, Taylor, & Brouillard, 1988). If this is so, such mediating variables may interact with levels of anxiety or negative affect to influence an individual's overall somatic response pattern elicited by threatening or stressful situations (Geen, 1997). Negative affect has been linked with increased emotion-oriented, passive, and maladaptive coping in both men and women; a more constricted, obsessive perspective; and less direct or problem-centered forms of coping. By contrast, extraversion has been associated with more direct or active coping, as well as with a broader attentional and behavioral repertoire that can marshal more resources for dealing with stressful conditions (Folkman & Moskowitz, 2000; McCrae & Costa, 1987).

One consequence of resorting to drug use in the presence of negative affect is that the latter may serve as a subsequent cue that is likely to elicit relapse. Such emotional signaling may derive in part from the addicted individual's previously formed associations or learned expectations that drug use will relieve aversive moods. It is also possible that negative emotional states may inhibit the allocation of non-automatic cognitive

and behavioral coping resources to the task of maintaining drug abstinence (Tiffany, 1990).

Taylor et al. (1997) found a relatively low but positive association between alexithymia and negative affect ($r = .29$) along with subscales on the NEO Personality Inventory (McCrae & Costa, 1987) reflecting tendencies to experience anxiety, depression, shame, and embarrassment as well as vulnerability to stress. In addition, alexithymics and individuals characterized by negative affect are also susceptible to somatization and general (undifferentiated) dysphoria (Taylor et al., 1997; Wickramasekera, 1988). However, unlike alexithymics, those who are high in negative affect are generally also very self-disclosing and introspective, given to ruminating on the unfavorable aspects of themselves and their experiences in the world (Watson & Clark, 1984). While high scorers on tests of negative affect may have difficulties managing affects because they are labile and, like alexithymics, relatively slow in returning to a normal physiological state after emotional experiences, problems with affect regulation among alexithymics also derive from their restricted emotional repertoire, diminished fantasy life, and concrete cognitive style.

Despite their differences, it is the commonalities between these traits that have led some to question the distinctiveness of the alexithymia construct from aspects of anxiety or depression, or the point of measuring it separately (Haviland, Shaw, Cummings, & MacMurray, 1988; Haviland, MacMurray, & Cummings, 1988; Mayer, Di Paolo, & Salovey, 1990). In fact, research points to alexithymia as both a secondary, reactive phenomenon and a continuous personality trait in different individuals. For example, while the scores of a group of inpatient male alcoholics on the Beck Depression Inventory dropped significantly 3 weeks after they entered treatment, their average mean scores on the original scale for alexithymia (the TAS-26) remained unchanged, a finding that might seem definitively supportive of alexithymia as a stable personality dimension. However, those patients who initially scored highest for alexithymia on admission had lower scores for it 3 weeks later, whereas just the opposite was true for those who initially scored the lowest on the TAS-26 (Haviland, Hendryx, et al., 1991; Haviland, MacMurray, & Cummings, 1988). It seems that for some of these individuals, alexithymia may have been a temporarily adaptive response to acute emotional distress and then subsequently subsided when the distress diminished, which would have been an expected result after 3 weeks in treatment. Alternatively, for others, the blunting of affect and other alexithymia-related charac-

teristics may simply have been offset initially by conditions that could precipitate a major emotional upheaval, as is often the case at the onset of treatment. The result might be relatively low TAS-26 scores that would subsequently increase as the distress was alleviated and the existing alexithymic tendencies reemerged (Haviland, MacMurray, & Cummings, 1988).

Prospective studies of medical and psychiatric populations provide further evidence that alexithymia is a stable and unique personality dimension rather than simply a byproduct of negative affect in the form of anxious or depressed mood despite some of its shared variance with both of these measures (Taylor et al., 1997). Significant correlations have indeed been found between scores on the TAS-26 and the Beck Depression Inventory in university students, newly abstinent alcoholics, and substance users; apparently, depression and anxiety are related to the factors on the TAS-26 that are associated with the identification and communication of feelings rather than externally oriented thinking or reduced daydreaming (Hendryx, Haviland, & Shaw, 1991; Haviland, Shaw, Cummings, & MacMurray, 1988; Taylor et al., 1997).

However, drawing from samples of both college students and psychiatric outpatients, a study involving two factor analyses of a correlation matrix that consisted of items from both the TAS-26 and Beck Depression Inventory found that these scales produced separate factors corresponding to their respective constructs. In another study, the Brief Symptom Inventory and the TAS-26 were administered to 54 patients at a psychiatric outpatient clinic, the majority of whom were diagnosed with and actively treated for either depressive or anxiety-related disorders. All those retested 1 year later showed significant decreases in psychological distress but no corresponding change in their mean alexithymia scores (Salminen, Saarijarvi, Aarla, & Tamminen, 1994). Thus, alexithymia and depression are distinct dimensions that are correlated moderately but measurable independently (Parker, Bagby, & Taylor, 1991). Awareness of alexithymia as a construct distinguishable from depression can possibly enhance the understanding of individuals who present with atypical or well-concealed (somatized) depressive and/or anxiety-related symptoms in medical treatment settings (Taylor et al., 1997; Wickramasekera, 1988).

In summary, while both negative affect and depression overlap somewhat with alexithymia, it appears that these constructs are broader personality dimensions that cannot capture some of its more specific aspects (Taylor et al., 1997). In any event, the physiological as well as emotional consequences of an impaired capac-

ity for affect regulation might explain the tendency of some individuals who are alexithymic or high in negative affect, or who show evidence of both dimensions, to cope with tensions from distressing states through impulsive, antisocial acts (Keltikangas-Jarvinen, 1982) and/or through escapist behaviors such as addictive drug use and overeating (Taylor & Bagby, 1988).

Alexithymia: Interpersonal Relatedness and Emotional Intelligence

As previously noted, besides simply involving difficulties in affect management, alexithymia may represent an impairment in the more generalized domain of emotional intelligence. The latter has been defined as a set of conceptually related cognitive skills that are essential to the accurate appraisal, communication, and regulation of emotion in oneself and others. Such skills also involve the adaptive use of feelings and moods as signals in helping to motivate, plan, and facilitate decision making (Goleman, 1995; Salovey & Mayer, 1989–1990).

If alexithymic individuals are largely unaware of their own subjective mood states, it is difficult to conceive how they can accurately describe these to others. Indeed, deficits in emotional regulation and interpersonal skills are inextricably linked (Matthews & Wells, 1996). Relatively lacking in affective communication, alexithymics may fail to elicit the support of the significant people around them, thereby missing an opportunity for appropriate regulation of affect (Taylor et al., 1997).

Moreover, if alexithymics are unable to identify or modulate painful feelings in themselves, they may be equally insensitive to these same manifestations of distress in others, and thus inept at providing empathy or solace, or helping to modulate the emotional states of their companions. Thus, awareness of feeling states, or insight regarding one's own internal environment, has been hypothesized to be highly related to insight into the emotional cues provided by others (Matthews & Wells, 1996). In one study, students in a high-alexithymia group, as identified by the TAS-20, were less able to recognize the emotions signified by posed facial expressions than those in the low-alexithymia group (Parker, Taylor, & Bagby, 1993).

A consistent association has been found between empathy and the ability to communicate emotion. Moreover, the capacity to recognize consensual emotion in faces, colors, and abstract designs is better among those higher in empathy, which itself is a ma-

jor aspect of emotional intelligence (Mayer & Salovey, 1993). Being able to anticipate the reactions and behavior of others should facilitate smoother, more rewarding interpersonal relationships and better overall social functioning, each of which has been associated with higher self-esteem (Davis, 1983).

Marked by deficits in both the cognitive-experiential and interpersonal domains of affect regulation (Taylor et al., 1997), alexithymia has been associated with reduced social support. In one study, the researchers found that all alexithymia factors, especially the one related to difficulty communicating feelings, were negatively related to social skills (Kauhanen, Kaplan, Julkunen, Wilson, & Salonen, 1993). Another study found that the alexithymia factors related to both the identification and communication of feelings were associated with less perceived social support and smaller actual social networks (Lumley, Ovies, Stettner, Wehmer, & Lakey, 1996). Presumably because of their interpersonal disengagement and inadequate social skills, those demonstrating alexithymic characteristics among both sexes turned out to have fewer intimate relationships, such as friends or steady partners. The researchers noted that while a relative inability to identify feelings was most directly connected with perceptions of poor social support, the alexithymic factor related to difficulty communicating feelings to others was most predictive of these individuals' constricted social networks (Lumley et al., 1996).

The alexithymic characteristics cited in these studies interfered only with those social relationships whose development and maintenance required interpersonal skills and emotional awareness, a finding that has implications not only for the intimate, and possibly professional or organizational, lives of alexithymics, but for their therapeutic relationships as well. Accordingly, interventions that emphasize greater awareness of an individual's emotional states and those of others along with better communication skills may lead to more sustaining relationships for alexithymics and reduce their risk of turning to inappropriate or self-defeating sources of support (Krystal, 1979; Lumley et al., 1996).

Like alexithymia, negative affect may be associated with aspects of emotional intelligence that involve empathy, interpersonal relatedness, and the perception of feelings in others (Mayer & Salovey, 1988). Since individuals who are high in negative affect are considered especially reactive and attuned to their own internal states, it might be presumed that they are more sensitive than alexithymics to the emotionality or shifting mood states of others as well. However, by intensifying

and thereby distorting whatever feelings they do perceive in themselves and others, they too may show limitations in both the intra- and interpersonal domains of emotional intelligence (Mayer & Salovey, 1988).

Although negative and positive affect are demonstrably independent personality variables (Watson, Clark, & Carey, 1988; Diener & Emmons, 1984), alexithymia has also been shown to correlate significantly and inversely with the tendency to experience positive emotions. This finding corresponds with clinical reports of alexithymics' limited ability to express feelings such as joy, happiness, and love (Krystal, 1988; Taylor et al., 1997.) However, alexithymia has been found to be associated with a diminished capacity to experience pleasure *only* in interpersonal contexts (Prince & Berenbaum, 1993). Based on the scores of alexithymic individuals on the Physical and Social Anhedonia Scales, the data of these researchers did not support the notion that alexithymics are incapable of experiencing pleasure *per se*, because no strong correlations were noted between alexithymia and measures of physical anhedonia. In their student sample, those who cited a diminished ability to interpret their own emotions reported *more* rather than less capacity for physical pleasure.

The association of alexithymia with an inability to experience pleasure in social as opposed to physical situations suggests that interpersonal rather than physical sensory processes may be implicated in the origins of this personality dimension (Prince & Berenbaum, 1993). Although the ability of individuals to fathom their emotional states is often assumed to be linked with an awareness of their internal physiological condition, these researchers suggest that alexithymia may not be the consequence of a failure simply to recognize one's internal states but rather may be linked with how such information is processed in the context of relationships with others. In addition, of all the emotions, anger, a feeling that can be understood mostly in an interpersonal context, has been most consistently associated with alexithymia (Prince & Berenbaum, 1993). Such findings appear to lend support to the idea that alexithymia and other disorders of affect regulation may often originate in an individual's earliest attachment relationships, in which interpersonal patterns of responses and expectancies are initially formed (Ainsworth, Blehar, Waters, & Wall, 1978; Goldberg, MacKay-Soroka, & Rochester, 1994; Keltikangas-Jarvinen, 1982; Khantzian & Treece, 1985; Priel & Shamai, 1995; Sroufe, 1985; Stern, 1985; Wilson, Passik, Faude, Abrams, & Gordon, 1989).

In general, each attachment pattern results in a particular style of affect regulation, and infants learn to

manage emotions in a manner best designed to maintain closeness with the parent figure (Main, 1990). Securely attached children whose mother or primary parent has been emotionally responsive, empathic, and consistent regard their caregiver as a "secure base" and a source of comfort or support from which to explore the world or regulate feelings of distress (Bowlby, 1988; Mahler, Pine, & Bergmann, 1975; Priel & Shamai, 1995). When such children do experience negative feelings or threats to their well-being, they express this openly and directly in anticipation of a nurturing, solacing response (Main, 1990).

In contrast, insecurely or ambivalently attached youngsters whose primary parents are emotionally unstable and unpredictable make inconsistent attempts to use their caregivers for comfort or support (Priel & Shamai, 1995). As a result, they may alternate between angry, resistant behaviors and intense attachment seeking but are unable to gain solace in a secure or lasting way because they sometimes evoke nurturing, and other times hostile or neglectful, responses from caregivers (Schaffer, 1993; Slade & Aber, 1992; Taylor et al., 1997). Avoidantly attached infants and children whose caregivers have been emotionally aloof and unresponsive learn not to rely on their mothers or primary parents as a source of solace to regulate negative affect. Instead, by minimizing any outward display of negative emotion, they ensure greater proximity to caregivers who may be least accessible or solacing when their demands for comfort are the greatest. In effect, some children learn to distort their own emotional spontaneity or expressiveness in an effort to conform to their parents' needs and limitations (Schaffer, 1993).

Regarding the neurobiological consequences of such early dyadic failures, Schore (1994) reports associations between infantile stress and significant reductions in the number of dopaminergic neurons in the ventral tegmental area, along with problems in other critical subcortical and cortical regions. These factors may heighten susceptibility to later drug use and related disorders that reflect impairments in the capacity for self-regulation, socioemotional functioning, and stress modulation. Indeed, the inhibitory effects of early infant-caregiver miscues may lead to poor planning, impulsivity, lack of affect tolerance, and dependence on exogenous opiates for self-soothing and regulation (Schore, 1994; Wilson et al., 1989).

Overall, insecure attachments and losses of early empathic care create a growth-restricting environment that may produce "immature, unevolved, physiologically undifferentiated . . . affect regulatory systems" along with personality and somatization disorders (Schore,

1994, p. 404). Affect regulatory disturbances may be of the uncontrolled (excitable, hyperreactive) variety associated with dominance of the sympathetic nervous system, or they may represent an overcontrolled, over-regulated, and emotionally restrictive pattern reflective of a parasympathetic bias. The degree to which the mother stimulates and modulates affect-arousal states and maintains these within a moderate range may influence the ongoing sympathetic-parasympathetic balance. While secure infants who are protected from extremely high and low arousal states develop an optimal balance between these two autonomic systems, avoidant and ambivalently attached infants are presumed to develop a bias or imbalance in favor of one system over the other (Schore, 1994).

Since the earliest image of the mother or caregiver in relation to the infant is considered the forerunner of the ability to fantasize, failure to develop an inner imaginal life may leave the child without the capacity for sustained self-soothing (Horton & Sharpe, 1984). This in turn may leave him or her at risk for the future development of a wide range of mood or behavioral dysfunctions such as depression, antisocial behavior, eating disorders, and substance dependence under certain stressful circumstances. Indeed, fantasies, dreams, interests, and play activities that eventually extend beyond the images derived from the caregiver and other external objects are transitional phenomena that may play an important role in regulating affect by organizing complex experiences into manageable forms to avoid extremes of emotional distress and generate positive feelings (Horton & Sharpe, 1984; Keltikangas-Jarvinen, 1982; Taylor et al., 1997; Trad, 1986). "Maternal soothing" and transitional relatedness play an essential role in the acquisition of language and linguistic competence along with other aspects of a child's development (Horton & Sharpe, 1984, p. 174).

There is strong evidence that the attachment styles of infancy and childhood remain relatively stable across the life span and may even be passed on from one generation to another (Goldberg et al., 1994.) Schaffer's research (1993) demonstrated that the individuals in both clinical and nonclinical samples who were identified as having a compulsive care-seeking attachment style scored highest on the original 26-item Toronto Alexithymia Scale, and those with a compulsive self-reliant attachment style were strongly alexithymic as well. Alexithymic individuals with either (unhealthy) attachment pattern tended to use oral or somatic ways of regulating emotional distress such as bingeing on food, drinking alcohol, or developing a physical symptom—none of which was considered a successful means of

coping by the users (Schaffer, 1993). Such activities are neither reflective nor rationally planned and may be considered examples of ineffective avoidance-oriented coping, as opposed to more appropriate and adaptive strategies. The alexithymic individuals were also least likely of all to engage in either interpersonal behaviors or fantasies to alleviate painful affects (Parker, Taylor, & Bagby, 1998).

Despite their repeated and acknowledged ineffectiveness as solacers, the alexithymics apparently resorted to oral and physical (avoidant) coping strategies as if they had only this limited "bag of tricks" at their disposal. By contrast, securely attached individuals showed low levels of alexithymia and regulated their emotional states most often by communicating directly with others as well as by imagining that they were doing so; both forms of coping were considered successful in managing affect and securing a desired outcome (Schaffer, 1993).

Similarly, alexithymic individuals reported using music, television, and other people for solace during times of stress significantly *less* often than a matched control group (Horton, Gewirtz, & Kreuter, 1992). The controls' next most frequently cited source of comfort—the memory of happier moments—was not even mentioned by the alexithymic group, a finding that appears to coincide with their reported inability to fantasize or recall symbolic dreams. The researchers concluded that alexithymics may have difficulty finding not only an adequate number of solacers, but also those of a mental or imaginal nature, as these were conspicuously absent from their list of comforting activities.

Besides faulty patterns of maternal-infant attachment and subsequent reinforcing events, specific neurophysiological deficits have been associated with alexithymia. As already noted, these factors may be interrelated, since critical phases in neurological development may be influenced by the quality of parent-child attachment and early childhood experiences.

Regarding the role of specific brain abnormalities, a discontinuity or impaired communication between the functions of the limbic system and the neocortex may prevent feelings originating in the hippocampal area from being relayed to the higher cortical brain regions for cognitive processing and evaluation, leading instead to their immediate expression through autonomic pathways. Thus, rather than developing a language for feelings, the affected individuals would likely communicate their emotional states somatically, or primarily through an "organ language" (Lesser, 1981; Nemiah, 1977; Taylor et al., 1991.) A well-functioning limbic system plays a role in modulating the experience and expression of

pain as well as emotion and is also rich in opiate receptor binding sites (Flannery, 1978). If alexithymia involves impairments in limbic functioning, sufficient levels of morphine-like substances, or endogenous opioids, may not be produced. Accordingly, alexithymic individuals in pain or distress who are lacking such internal modulators may seek to reestablish homeostasis through external means, which potentially include the misuse of drugs or alcohol (Flannery, 1978).

Based on prior observations of a paucity of fantasy and a poor ability to symbolize in “split-brain” (surgical commissurotomy) patients treated for severe epilepsy, some researchers have suggested that individuals with pronounced alexithymic behavior may suffer similarly from a lack of interhemispheric communication whereby the essentially nonverbal right hemisphere ends up hypercathecting physical sensations blocked from the left hemisphere’s verbal processing ability (Lesser, 1981; TenHouten, Hoppe, Bogen, & Walter, 1986.)

As reported by Lesser (1981), other evidence from a study of cerebral laterality with subjects who were exposed to painful stimuli and monitored with electroencephalography (EEGs) studies showed that activation of the left hemisphere was associated with an increase in pain, whereas right-hemisphere stimulation was associated with both decreased pain and utilization of fantasies, following the experimenter’s instructions. It appeared that the instruction to use fantasy was the key factor in one group of subjects’ ability to tolerate pain better than their non-fantasizing counterparts. This finding suggests that individuals who are unable to escape through imagination or fantasy from their immediate circumstances may experience more prolonged and less tolerable distress than those who can mobilize this natural coping technique (Lesser, 1981), which is presumably relevant to the management of both physical and emotional pain. With our increasing awareness that the processing of emotions, imaginal activities, and other cognitive functions involves the successful integration of both hemispheres, it seems likely that alexithymia will be shown in the future to reflect a “deficiency in how the two hemispheres coordinate their respective operations” (Taylor et al., 1997, p. 113).

Alexithymia, Affective Disorders, and Substance Use

Khantzian (1990) and Lynch (1985) noted that substance users are often “disaffected,” or unattuned to their own emotional signals, and a number of researchers have pointed to a higher than usual incidence of alexithy-

mia among people who become addicted to alcohol or mood-altering drugs and/or who are prone to relapse (Giannini, 1996; Haviland, Hendryx, Shaw, & Henry, 1994; Haviland, Shaw, MacMurray, & Cummings, 1988; Loas, Fremaux, Otmani, Lecercle, & Delahousse, 1997; Rybakowski et al., 1988; Taylor et al., 1990; Ziolkowski et al., 1995).

Using the 26-item TAS, Haviland et al. (1991) found alexithymia in 50.4% of men with mixed substance use disorders. Although no significant difference was noted in the severity of drug dependence per se between the alexithymic and non-alexithymic groups, the former presented significantly more physical complaints and general “psychological turmoil,” including anxiety and depression, and less ego strength than the extremely non-alexithymic individuals. The latter were less socially constricted, more verbally and socially adept, and apparently more skilled at using repressive (coping) mechanisms.

One important finding of this study was that alexithymic characteristics cannot be attributed to a repressive coping style or the excessive use of denial but rather represent a distinct clinical entity whereby low scores in alexithymia are more associated with repression of affect than are high scores. (The section on repressive coping and alexithymia later in this chapter addresses the differences between these two constructs.) The substance-dependent alexithymics in this study might also be described as engaging in a relatively primitive pre-conceptual level of affect regulation by somatizing or “acting out” their feelings instead of grasping them through communication with themselves and others (Lane & Schwartz, 1987). Indeed, if language is a means through which experience is not only represented but also processed, transformed, and even transcended, it is not surprising that alexithymics, with their relative incapacity for symbolization, may choose alcohol or drugs to compensate for their failure to modulate distressing emotional states.

Khantzian (1990) observes that many substance users suffer from feeling either too much or too little; others are overwhelmed by intense affects or alternate between the extremes of “emotional flooding and emptiness” (p. 258). Krystal (1979) notes that chemically dependent patients with alexithymic tendencies appear decidedly uneasy not only with words that convey emotion but with the physiological aspects of feelings as well. Those who fail to verbalize or reflect upon their feelings or who view them as essentially threatening instead of as vital signals that can prompt some form of self-correction may become hypochondriacally obsessed with the somatic accompaniments of emotional

arousal and the strictly physical discomforts associated with their condition. Chronic relapse is an all too likely consequence of any compulsive quest to block these affectively and somatically painful sensations (Krystal, 1975).

Studies by Loas et al. (1997) and Rybakowski et al. (1988) found an especially high prevalence of alexithymia in alcohol-abusing subjects (78% and 67%, respectively). In each case, researchers noted that individuals with a shorter duration of abstinence were more alexithymic than those who maintained sobriety for longer than 1 year. In the first study, the difference in alexithymia between alcoholics and abstinent remained significant even after the researchers controlled for depressive symptoms.

According to the adaptive orientation, coping, and self-medication models of substance use (Alexander & Hadaway, 1982; Goleman, 1995; Khantzian, 1985; Milkman & Frosch, 1973; Pentz, 1985; Pervin, 1988; Tarter, 1988; Wurmser, 1974), the majority of addicted individuals choose their drug(s) purposively to protect themselves from unpleasant states of self-awareness in stressful environments, compensate for some specific emotional deficit or excess, and/or enhance their subjective well-being. These individuals may form long-term "attachments" to these substances in their ongoing search for emotional and self-regulation. Whereas the self-medication perspective emphasizes the management of painful affects, other self-regulating factors involving self-esteem, interpersonal relationships, and self-care in connection with affect states are also relevant to "substance use and misuse" (Khantzian, 1990, p. 257). Wurmser (1974) noted the effectiveness of opiates in countering feelings of shame and social isolation. For other users, heroin may be desired not primarily for its euphoric effects but rather for its capacity to reduce aggression and rage and thus to ease intense internal distress along with impulses toward antisocial behavior (Khantzian, 1985, 1993; Khantzian & Treece, 1985). In addition, some opiate users may suffer from a depletion of endogenous opioids, the neurotransmitters that drugs like heroin mimic in the brain, and low levels of these chemicals are related to anger and agitation (Goleman, 1995). It is possible that such biogenetic susceptibilities resulting from irregularities in brain neurochemistry alone or from the latter together with the influence of early familial and social experiences can lead to lifelong difficulties handling negative affects (Kotulak, 1996).

Those who experience their emotions in a less differentiated or sophisticated and more diffused manner may not recognize and seek to regulate specific painful feeling states such as anger or shame but rather may be

drawn to the more concrete consequences associated with drug use itself, such as physical withdrawal or a chaotic, high-risk lifestyle. The latter may be seen as a more concrete, comprehensible, and controllable forms of suffering—preferable to the nameless, often bewildering mix of emotions that may leave one feeling overwhelmed and out of control (Khantzian, 1990, 1993).

While itself a form of avoidant coping, substance use may also be the consequence of more global deficits in coping skills. Avoidant types of coping in general may predispose to or accompany chemical dependence because the individual is not prone "to deal with problematic situations, but rather to seek the path of least resistance toward restoring affective balance" (Wills & Hirky, 1996, p. 284). In general, more active or direct types of coping (task focused, cognitive, and social) are believed to decrease the risk of substance dependence, especially initiation and relapse, because these approaches are more likely to resolve difficult situations, heighten self-efficacy, and encourage others to assist in the problem-solving process. These outcomes can lead to a cycle of successful results that reinforce further active coping efforts (Wills & Hirky, 1996).

Given their ineffective coping skills and emotional dysregulation, many chemically dependent individuals have impaired relationships with themselves, as they are often grossly lacking in the capacity for self-care and self-soothing (Horton, Gewirtz, & Kreuter, 1989; Krystal & Raskin, 1970). As noted previously, perhaps deficiencies in experiences with caregivers during their early development left such individuals without the image of a comforting maternal object that they could internalize and draw upon—a form of cognitive coping—when temporarily distressed. For people who lack the capacity to "mother" themselves through internally generated means, the attraction of drugs that can provide immediate and profound relief from such displeasure is obvious and compelling. Such incapacity for self-soothing may also account for substance users' commonly observed dread of being alone and the often compulsively pursued, excessively dependent, and symbiotic (or addictive) nature of their relationships. The ambivalence and conflict inherent in these interpersonal connections may be evident, as these individuals may idealize the kinds of maternally close relationships that eluded them as infants yet at the same time also dread them. Such a paradoxical coupling of overdependence and distrust possibly points to the persistence in adulthood of early insecure-ambivalent and insecure-avoidant attachment styles (Taylor et al., 1997).

While substance users' relationships with others are often marked by deficits in affect regulation and

emotional intelligence, research suggests some important differences, depending on drug of choice. For example, individuals who are addicted to heroin, like the clinically depressed, have been found to be significantly less adept than non-users at interpreting non-verbal emotional cues, while those who are dependent on cocaine and alcohol, like manic individuals, have shown increased affective interpretive abilities (Gianini, Folts, & Feidler, 1990; Giannini & Sangdahl, 1985). It is possible that the depressant, sedating effects of opiates may render many addicted individuals less sensitive or attentive to the emotional reactions of others, or possibly the kinds of people who are drawn to heroin in the first place may lack this interpersonal competence. Noteworthy are studies showing that programs that stress interpersonal communication skills for heroin users have a lower relapse rate than programs without this intervention (Heather, Edwards, & Hore, 1975).

ABSORPTION

Absorption is a relatively broad dimension of personality denoting a disposition for having episodes of total attention that fully engage one's perceptual, imaginative, and ideational capacities (Nadon, Hoyt, Register, & Kihlstrom, 1991; Tellegen & Atkinson, 1974). Absorption has been consistently albeit only moderately correlated with susceptibility to hypnosis and is characterized by intensity of focus, imperviousness to distracting events, and the potential for an empathically altered sense of self (Kihlstrom, Register, Hoyt, Albright, Grigorian, Heindel, & Morrison, 1989; Tellegen & Atkinson, 1974). It has also been described as a pronounced quality of involvement that can be differentiated from one's ordinary experience with an attentional object (Wild, Kuiken, & Schopflocher, 1995). Research has suggested that absorption entails a desire and readiness for affective engagement (Roche & McConkey, 1990), thereby positioning it somewhat in contrast with alexithymia, which, as noted earlier, involves an emphasis on mundane or banal environmental details, or concrete thinking, an absence of differentiated feelings, and an impoverished imagination (Lesser, 1981).

Tellegen and Atkinson (1974) introduced the Tellegen Absorption Scale (TAS), which has since been included in Tellegen's (1982) comprehensive Multidimensional Personality Questionnaire. More recently, Tellegen (1992) has defined absorption as a disposition to enter under conducive circumstances psychological states that are characterized by marked restructuring of the phenomenal self and world.

These more or less transient states may have a dissociated or an integrative and peak-experience-like quality. They may have a "sentient" external focus or may reflect an inner focus on reminiscences, images, and imaginings. The absorption trait subsumes these diverse possibilities in a remarkably cohesive correlational structure (Tellegen, 1992, p.2).

Beyond simply an ability to commit attentional resources to particular events or objects, items on the TAS have been shown to tap an inclination for both dissociative and holistic, or integrative, experiences and ways of processing information that involve both the narrowing and broadening of attentional focus as well as an experiential (vs. instrumental) orientation (Kihlstrom et al., 1989; Tellegen, 1992). People practicing meditation have been found to score higher on the TAS than non-meditators (Davidson, Goleman, & Schwartz, 1976). Studies on the relationship between biofeedback and relaxation have found that when high-absorption people are instructed to direct their attention toward a biofeedback signal or an experimenter's instructions, their physiological and cognitive indices of relaxation are inhibited. Apparently, the distracting signals or direct, explicit instructions can interfere with their inwardly focused attention, withdrawal from external stimuli, and use of self-generated, affectively toned imagery. By contrast, low-absorption subjects can relax optimally *only* when they adopt a reality-oriented, goal-directed mindset in which their attention is directed outward, either toward explicit instructions or a signal (Qualls & Sheehan, 1979). For individuals who are high in absorption, the external interference can be overcome by suggestions to use imaginal strategies that creatively incorporate the signal into their own internal experiences (Qualls & Sheehan, 1979).

Tellegen (1992) notes that the way absorption manifests itself in individuals often depends on their characteristic (positive or negative) affect or temperamental style along with their experiential history; thus, the cognitions, perceptions, and experiences of high-absorption individuals may be primarily integrative or disruptive, creative and expansive, or inflexible and self-limiting. Despite these individual differences, those with relatively high capacity for absorption may be more emotionally reactive and aware of feelings, and less likely to somatize or be susceptible to organic disease than those who are relatively low in this characteristic (Wickramasekera, 1995).

Costa and McCrae (1987) found a negative correlation between a measure of alexithymia called the Schalling-Sifneos Personality Scale and the personality dimension known as openness to experience, noting

that elements of the latter include an active imagination, aesthetic sensitivity, attentiveness to inner feelings, and psychological-mindedness. It was also observed that openness is positively linked with divergent thinking, creativity, and absorption. Scores on the TAS were found to be most closely associated only with those aspects of openness that relate to fantasy, dreams, imagery, awareness of inner feelings, and other aspects of attention and consciousness, rather than those related to intellectual curiosity, openness to unusual ideas, or liberal values (Glisky, Tataryn, Tobias, Kihlstrom, & McConkey, 1991). Since absorption and its related subscales of openness were positively correlated with hypnotic ability, whereas the latter was not shown to be associated with the remaining aspects of openness, the construct known as openness to experience may represent not one but rather two dimensions of personality that have become "inadvertently conflated" on present measures and should be considered separately (Glisky et al., 1991, p. 271).

If certain individuals have difficulty becoming absorbed, they may not have access to internal and potentially effective means of coping with stressful events, such as through refocusing, visualization, relaxation, fantasy, or any other self-soothing approaches that involve a shift in consciousness and may facilitate self-disclosure. Chaves and Brown (1978) reported an association between absorption and the spontaneous cognitive strategies utilized by individuals for the regulation of both clinical pain and stress. As noted earlier, individuals who are low in absorption may develop a very restricted repertoire of coping skills confined typically to behavioral methods such as feeding and drinking to regulate aversive feelings (Wickramasekera & Price, 1996). Thus, it is possible that people who have low capacity for absorption may turn to mood-altering drugs to achieve the kind of internal emotional management that they simply cannot attain on their own. Conversely, however, one potential advantage of low absorption is that it may be associated with less suggestibility and automaticity than is hypnotic ability and possibly also high absorption (Evanow, Saap, Pumphrey, Jones, Edwards, & Pitsch, 1998). Accordingly, low capacity for absorption may be associated with relative unawareness of or insensitivity to the influences of other individuals or external events, which could be implicated in drug use and relapse experiences.

As for the antecedents of absorption, just as the inhibition of verbal expressions of affect within families may be related to the later development of alexithymic characteristics, so is parental encouragement of imaginative activities during childhood associated with

high capacity for absorption (Hilgard, 1974). It is also possible that the persistence of emotional isolation or severe abuse during childhood may lead to the use of attention-engaging imaginative play and a propensity for fantasy to achieve self-protection and regulation of disturbing affect (Lynn & Rhue, 1986, 1988; Rhue & Lynn, 1987).

Since absorption has been associated with the capacity for sustained attentional involvement as well as reduced distractibility in the presence of other stimuli, the TAS may offer a way of accounting for individual differences in the cerebral concomitants of selective attention (Davidson, Schwartz, & Rothman, 1976). For example, high or low scorers on the TAS (representing the top or bottom 8% of the sample) were requested to attend to or count either visual or kinesthetic stimuli (flashing lights or tapping sensations) while an EEG was recorded for both the occipital and motor areas of their brains. In contrast to the low-absorption participants, the high-scoring ones showed significant differences in EEG ratios when the conditions involving the counting of the visual signals were compared with the counting of kinesthetic stimuli. This suggested greater "cortical specificity" among those who were high in absorption than among those who were low in this measure (Davidson, Schwartz, & Rothman, 1976).

Such hemispheric specificity while engaged in a cognitive task was primarily a function of the ability of the high absorbers to inhibit activity in the (irrelevant) visual region during the kinesthetic counting exercise. By contrast, subjects falling on the low end of the distribution on the TAS appeared to have more difficulty resisting distraction from irrelevant modalities when facing increased task demands for mode-specific attention (Davidson, Schwartz, & Rothman, 1976). It is possible that conditions requiring simple attention differ from those involving the more demanding task of counting in the quality as well as degree of attention required to complete the activity. Thus, high-absorption individuals may be more skilled at engaging in this effortful type of selective attention but not necessarily more adept than those who are low in absorption when it comes to tasks requiring simply receptive attention (Davidson, Schwartz, & Rothman, 1976). Recent neurophysiological findings have also provided evidence that while the right hemisphere plays a role in the affective components of dreams, fantasy, and visualization, each of which is associated with absorption, the left hemisphere is involved in the verbal organization and narrative structure of these same imaginative activities. Thus, the generation of mental imagery involved in absorption is believed to require the activation of and

close collaboration between both cerebral hemispheres (Taylor et al., 1997).

As with alexithymia, questions have been raised about whether absorption can be considered a transient state influenced by external circumstances as well as an enduring personality characteristic. For example, scores on the TAS have significantly changed following periods of isolation or even recent marijuana use (Roche & McConkey, 1990). Moreover, the TAS itself may not capture the kinds of experiences in which concrete-minded individuals can or do become intensely engaged (Roche & McConkey, 1990).

SELF-CONSCIOUSNESS

While alexithymia, low absorption, and deficits in self-awareness—all of which may involve impairments in the regulation of emotional states and self-soothing—may be risk factors for chemical dependence, the same may be true of atypically *high* levels of self-consciousness as well as high capacity for absorption in combination with negative affect.

When self-aware, some individuals are more apt to focus on the covert, internal aspects of the self, such as their own thoughts, feelings, desires, intentions, and values. Other individuals in a self-aware state attend more to themselves in a public context, such as their appearance, social demeanor, and the impressions they make on others (Fenigstein, 1997). Subjects high in private self-consciousness have been shown to respond more intensely to transient affective states than those who are low in this dimension (Turner, Scheier, Carver, & Ickes, 1978) while individuals high in public self-consciousness are demonstrably more sensitive to peer group rejection (Turner & Peterson, 1977). Private self-consciousness has been correlated with thoughtfulness, reflectiveness, and the use of visual imagery in dealing with personal problems (Turner et al., 1978), as well as with self-descriptions that are usually more detailed, extensive, and accurate, although distortions in self-concept are also possible (Fenigstein, 1997). Indeed, focusing on the self in some situations may increase the need to protect feelings of self-worth and avoid blame or escape any perceived negative aspects of the self (Fenigstein, 1997; Greenwald, 1980).

Thus, while self-consciousness can facilitate insight into one's own emotional experience as well as self-disclosure (Franzoi & Brewer, 1984), both of which are valuable in any intimate interpersonal and therapeutic context, sometimes the end result can be biased judgments regarding causality, yielding either exaggerated

self-attributions or behaviors that safeguard self-esteem (Fenigstein, 1997). Self-consciousness is also associated with lower susceptibility to placebo effects, presumably because negative physiological sensations are more clearly experienced when attention is predominantly directed toward the self (Fenigstein, 1997).

Duval and Wicklund's (1972) argument that self-consciousness per se is highly correlated with negative affect was not supported in subsequent literature. Franzoi and Brewer (1984) found that people high in self-consciousness showed only negligible differences in anxiety and emotionality compared to those who are low in this dimension. Carver and Glass (1976) reported that scores on each of the three subscales of the Self-Consciousness Inventory (measuring private and public self-consciousness and social anxiety) were independent of other measures, including emotionality, impulsivity, and test anxiety. However, high private self-consciousness might sometimes make it difficult to engage in positive or self-deceptive illusions. Thus, in an affectively negative context, self-focused attention may potentially heighten an individual's distress by intensifying awareness of painful realities and rumination about dysphoric emotions (Fenigstein, 1997; Wood, Saltzberg, Neale, Stone, & Rachmiel, 1990). Any relationship between self-consciousness and distress is likely to be reciprocal, as heightened negative affect and awareness of personal shortcomings are themselves apt to increase self-focus (Carver & Scheier, 1981). Moreover, whenever strong affect of any kind is being experienced, self-attention has been found to intensify the salience of that affect (Fenigstein, 1997).

While self-scrutiny can amplify existing negative moods and increase attentional bias to negative information about both the self and the environment, intensely happy moods can also be followed by shifts of attention inward. In both cases, such a change in perspective may promote cognitive and behavioral activities that potentially maintain pleasant, or alleviate unpleasant, mood states (Salovey & Mayer, 1989–1990).

According to Turner and Peterson (1977), individuals who are low in private self-consciousness are less willing to engage in self-focused attention and attend more to novel outer-directed feelings when their dominant affect is negative. However, individuals who are high in private self-consciousness remain self-focused and mull over thoughts and feelings about themselves regardless of whether their affective quality is negative or not.

Self-awareness is one of many variables that aid in the self-monitoring of behavior, and self-aware individuals are more likely to regulate their behaviors so that

they are consistent with salient normative personal or social standards (Beaman, Klentz, Diener, & Svanum, 1979; Carver & Scheier, 1981). Thus highly self-focused individuals are believed to accomplish self-regulation in part by comparing their current behavior with an accepted standard. Their actions or coping strategies become directed toward reducing any discrepancy between their present behavioral state and the recognized norm. When the perceived probability of reducing that discrepancy is low, negative affect is a likely consequence. But when there are expectations of success, self-consciousness should result in problem-focused or task-oriented coping (Carver & Scheier, 1981).

Thus self-focus may interact with perceptions of the likelihood of success or degree of confidence in its influence on coping as well as affect. In one study, self-focus was found to enhance performance on a puzzle-solving task among individuals with low test anxiety (i.e., in those with expectations of competence) but to impair performance among individuals with high test anxiety (Carver, Peterson, Follansbee, & Scheier, 1983).

The link between private self-consciousness and coping is not surprisingly somewhat complex (Matthews & Wells, 1996). Individuals with affective disorders are more vulnerable to an overload or diversion of critical attentional resources resulting from self-focus because of their tendencies toward anxiety and thus are more likely to engage in passively avoidant or excessively ruminative response and coping styles that can perpetuate rather than alleviate distress. Such individuals typically fail to increase use of active problem-solving approaches or adaptive emotion-focused strategies such as reappraisal, as would normally be expected, even when situations present themselves as having the potential to change (Matthews & Wells, 1996). Ultimately, whether patterns of coping used by privately self-focused individuals are dysfunctional or effective appears to depend on a combination of factors, including how they appraise situations and manage attentional demands as well as how prone they are to anxiety.

SELF-CONSCIOUSNESS, ABSORPTION, AND SUBSTANCE USE

A connection between capacity for absorption and heightened private self-consciousness, or a tendency toward "thinking introversion," was noted in a study of "creative blocks" (Barrios & Singer, 1981). In reporting only a moderate relationship between the ability to summon mental imagery and absorption, Roche and McConkey (1990) explain the discrepancy by sug-

gesting that imagery per se appears to require less of a "commitment of the self" to an imagined event than does absorption; thus high imagery ability alone does not necessarily mean one is able to connect that image with the self. It is conceivable that people who are high in absorption appraise information in a distinct way that associates it with the self and are inclined to attribute personal meaning to events that do not necessarily have any special relevance to themselves (Roche & McConkey, 1990).

One recently proposed theory maintains that alcohol use is often motivated by the desire to avoid painful states of self-awareness. Studying the links between chemical dependency and self-consciousness, Hull (1981) has shown that both the acute and long-term use of alcohol can reduce self-awareness by inhibiting cognitive processes related to the organization and encoding of information according to its self-relevance. Moreover, alcohol decreases the tendency to evaluate the self on the basis of past performance and to form negative self-judgments (Hull, 1987). If alcohol or drugs are effective in reducing self-awareness, it is conceivable that individuals with high levels of self-awareness and a propensity for negative self-relevant information processing or high negative affect may be at elevated risk for alcohol or illicit drug consumption.

In a study of individuals completing an inpatient detoxification program, the incidence of relapse among those who were high in private self-awareness was significantly related to the occurrence of negative self-relevant life events. By contrast, negative self-relevant life events were not significantly related to drinking behavior among those who were low in self-awareness (Hull, Young, & Jouriles, 1986). People who have relatively low or fragile self-esteem, a characteristic associated with trait negative affect, and are also high in self-consciousness may be especially susceptible to the need for chemical-based relief from painful self-assessments (Hull, 1987). As already noted, self-awareness alone has also been associated with increased emotional responsivity to affect-arousing situations (Scheier & Carver, 1977), which may be another impetus for chemical abuse. However, in the absence of negative self-judgments, highly self-aware individuals may not be motivated to reduce their self-consciousness (Hull & Levy, 1979) and thus would not be expected to show higher rates of alcohol or drug consumption.

It seems apparent that highly self-conscious individuals who are also high in negative affect may be too distracted by concerns about the self to be capable of either successful affect regulation or accurate self-appraisals. Effective interventions for such individuals

may involve rechanneling their insightful capacities in a more *outwardly* oriented direction and away from obsessive attention to the self. Moreover, transcendence, or the capacity to focus awareness beyond immediate situations and self-concerns, is often a vital aspect of emotion regulation (Baumeister & Heatherton, 1996).

Such awareness does not necessarily involve ignoring or denying the immediate present but rather means viewing it in the context of longer-range goals, values, and motivations; such ability is associated with the delay of gratification and with the use of cognitive restructuring, imagination, and visualization. For the excessively self-conscious who may turn to drugs and alcohol to reduce self-awareness and self-monitoring, the result may be a chemical form of myopia, because attention “under the influence” often becomes limited to a few immediate stimuli that can impede the kind of long-term, abstract, meaningful, and mentally flexible thinking involved in transcendence (Baumeister & Heatherton, 1996).

Although it has not been validated empirically, the concept of flow, which has been described as the capacity for optimal experience by Csikszentmihalyi (1990) seems to coincide in many respects with absorption and perhaps inversely with negative affect as it describes the ability to concentrate psychic energy and enter into a heightened state of consciousness with the capacity for sustained, outer-focused, and self-altering attention. Schizophrenics and other individuals with attentional disorders who respond indiscriminately to everything and experience “stimulus overinclusion” may be incapable of experiencing flow (Csikszentmihalyi, 1990, p. 84).

Similarly, individuals who are excessively self-conscious in a public way, or overly concerned about how they are perceived by others, may also be excluded from flow experiences, as are people who are too privately self-conscious and evaluate every bit of information in terms of how it relates to their personal aims, interests, or desires. If, according to Goleman (1995), flow is a state of self-forgetfulness, the opposite of rumination and worry, people who are too self-involved may not possess enough control of psychic energy to enter easily into a mentally expansive flow experience: as Csikszentmihalyi (1990) observes, “Too much psychic energy is wrapped up in the self, and free attention is rigidly guided by its needs” (p. 85).

Thus, flow—and perhaps absorption, or intense self-forgetful involvement in an activity or experience—may not be possible if attention to both self and environment is either too fluid and erratic, or too rigid and tight. Based on such observations about flow, it might

be concluded that people who are reasonably self-aware and high in absorption but *not* high in negative affect may have the potential for engagement in certain life experiences that make them less susceptible than usual to the escapist appeal or artificial highs offered by addictive drugs.

Another ability associated with absorption is a form of heightened awareness identified as “surplus pattern recognition,” which can be a sign of unusual creative potential in the arts or sciences because it denotes an ability to discern meanings and patterns not readily apparent to the average individual (Wickramasekera, 1998). However, those with good capacity for absorption who are concurrently high in negative affect may be prone to recognizing a surplus of *negative* patterning, or to finding personally aversive meanings in events that come across as neutral, random, and disconnected to others (Wickramasekera, 1994, 1998). Consequently, this tendency can intensify negative responses to even minimal or neutral sensory and visceral stimuli (Wickramasekera, Pope, & Kolm, 1996). Such obsessive thinking and accompanying negative affect have been targeted in some cognitive-based therapies for substance users in both group and individual settings (Swiller, 1988).

Instead of amplifying or catastrophizing about even minimal threats, individuals who are high in absorption without accompanying negative affect may be able to inhibit or even erase aversive stimuli from consciousness through a form of self-induced analgesia or amnesia (Wickramasekera et al., 1996), thereby isolating ongoing experience from external reality and critical self-appraisal (Kihlstrom et al., 1989). The result may be less reliance on external sources of solace, including chemical dependence.

Capacity for high absorption has also been linked with a dimension known as intrinsic religiosity, or an internal religious/spiritual focus, as opposed to an extrinsic and more conventional orientation, the potential for self-soothing, meditation, and mind/body healing, and the strength of the placebo response, possibly because of absorption’s relationship with conditionability and suggestibility (Davidson, Goleman, & Schwartz, 1976; Levin et al., 1998). Those who are inclined toward meditation or intrinsically religious concerns may have an advantage with regard to recovery from chemical dependency, and possibly less initial susceptibility to addictive drug use (Gorsuch, 1995; Mathew, Mathew, Wilson, & Georgi, 1995). Accordingly, as already noted, high absorption *alone* would actually appear to be a potentially protective factor in reducing someone’s vulnerability to chronic drug use as well as facilitating recovery.

In summary, alexithymic individuals who are low in private self-consciousness, or out of touch with themselves both physically and emotionally, might be prone to substance use disorders because they cannot verbalize, transcend, or symbolically mediate their emotional distress and so require an artificial means of relief. If their distress takes the form of more concrete physical symptoms, this may give them all the more reason for reliance on a chemical remedy. However, their extreme counterparts—especially those who are high both in absorption and aversive affect or who are intensely self-aware in a negative way—may also be drawn to the consciousness-inhibiting effects of addictive agents. Thus both kinds of individuals may engage in addictive drug use for essentially contrasting reasons.

REPRESSIVE COPING

It has been proposed that certain so-called social desirability scales such as the Marlowe-Crowne Social Desirability Scale (MC) and the Lie Scale of the Eysenck Personality Inventory actually measure a substantive individual difference variable consisting of affect inhibition, defensiveness, and protection of self-esteem (Lane et al., 1990; Weinberger et al., 1979). Accordingly, such scales may provide a major step toward discriminating between people who are truly low in anxiety and those who repress negative affect (Weinberger et al., 1979). Individuals who score low on these scales and concurrently low on scales measuring negative emotions may be genuinely low in subjective and behavioral responses to emotional distress, or low in negative affect (anxiety, tension, anger, and depression). Those who score high on these scales and low on scales measuring negative emotions are apt to be denying these unpleasant mood states through a repressive coping style (Weinberger et al., 1979; Wickramasekera, 1998). Objective indices show that repressors may experience levels of physiological reactivity that are equal to or even greater than those of people reporting high negative affect (Weinberger, 1990).

While individuals who score low on scales of social desirability and high on scales of negative emotion may be considered truly high in anxiety, those who score high on both types of scales may be identified as “defensive high anxious” individuals (Weinberger, 1990); hence high scorers on the MC scale may be thought of as either defensive or repressive copers, depending on how they perform on scales measuring negative emotion.

The MC scale measures the capacity for blocking negative perceptions, memories, and moods from

consciousness, a process that appears to operate by promoting inattention to aversive situations and by amplifying positive situations (Weinberger et al., 1979; Wickramasekera, 1988, 1998). It should be noted that the MC scale does not appear to identify those who are most likely to distort their responses to survey questions deliberately to impress others, as high scorers have been shown to believe what they are reporting—that is, that they are adjusted, extraordinarily well controlled, responsible, and not experiencing negative emotions of any kind—and attempt to behave accordingly despite objective evidence to the contrary (Crowne, 1990; Lane et al., 1990; Weinberger, 1990). Even when research designs maximize the conditions for private self-evaluations or employ a “bogus pipeline” technique (informing respondents that an instrument can detect if they are lying), high MC scorers still report less negative affect than a low-anxiety group (Weinberger, 1990).

The idea that some people sincerely do not recognize their own negative affective reactions challenges the traditional view of the brain as the source of unified cognitive processing, or the conceptualization of emotion as the result of linear interactions between the arousal system and the cognitive-interpretive system (Weinberger, 1990). However, recent work in cognitive psychology on parallel, neural network, and sequential-stage models of information processing can accommodate the idea of separate cognitive pathways prompted by the same stimulus (Greenwald, 1997; Hilgard, 1986). In addition, studies of brain subsystems from a psychobiological perspective suggest that emotions may derive at least partly from subcortical areas, including the limbic system, which can function somewhat independently of the verbal information-processing centers associated with the more recently developed neocortex (Weinberger, 1990, p. 340).

The demonstrated specialization of affect within the neocortex also plays a role. For example, negative/avoidant emotional responses in right-handed individuals are associated primarily with the activation of the frontal region of the right cerebral hemisphere. The latter is interconnected with the brain’s nonverbal limbic system, the judgments of which may sometimes be functionally disconnected from those represented by the left hemisphere’s verbal, and especially positive/approach, response centers (Schwartz, 1990; Weinberger, 1990). Such a “split” between the cognitive-affective and verbal systems can certainly result in “discrepant assessments of the same stimuli” and thus may account for the phenomenon of repressive coping (Weinberger, 1990, p. 341).

High scores on the MC scale may denote a consistently defensive or repressive coping style, discrepancies between subjective positive verbal reports and physiological indices of distress, and a relatively poor memory for negative emotional experiences in favor of positive ones (Lane et al., 1990; Weinberger et al., 1979; Wickramasekera et al., 1996). One possible limitation of the MC scale is that it may be able to identify only a subset of repressive copers, as it largely measures a personality style characterized by oversocialization and overcontrol, or the repression of impulse and affect. As Weinberger (1990) explains, most of this scale's items "refer primarily to the extreme inhibition of one's own needs when they are in conflict with the needs of others" (p. 368). However, repressiveness and denial may also be expressed through inadequate socialization and control, as in the case of individuals with narcissistic and/or histrionic personality disorders and adolescents with conduct disorders (generally considered precursors to adult antisocial tendencies), or they may surface in domains unrelated to either socialization or affective expression (Shedler, Mayman, & Manis, 1993).

There is evidence that the excessively socialized and affectively restrained high scorers on the MC scale are "especially unlikely to attend to information that might alter their positive self-images" (Weinberger, 1990, p. 349). Such repeated, unacknowledged defensive maneuvers to maintain control and avoid awareness of negative stimuli or anxiety may paradoxically interfere with effective coping and leave these individuals open to developing physiological as well as behavioral symptoms of distress (Lane et al., 1990; Weinberger, 1990). However, if repressors are seeking firm control over affects and impulses, they may also be less prone to addictive drug use, as one would not expect them to favor the disinhibition that often results from psychoactive substances, an observation that has been substantiated by several studies of drug and alcohol use among repressive college students (Weinberger, 1990).

Repressors may be less susceptible to addictive drug use and perhaps more readily inclined to emotional equanimity for neurophysiological reasons as well. In a study demonstrating the "opioid peptide" hypothesis, individuals identified as repressive were shown to have greater central endogenous opioid system activity, which may account for their reports of reduced distress, higher pain tolerance, and accentuated positive affects compared to those with lower levels of centrally active opioid peptides (Jamner, Schwartz, & Leigh, 1988). Like their repressive counterparts, the defensive high-anxious group also had elevated endogenous opioid levels but turned out to be "failed repres-

sors" with relatively ineffective coping mechanisms, an assessment supported neurobiologically by the finding of significantly greater urine and serum levels of corticosteroids (a stress-related neuroendocrine response) in these individuals than in repressors as well as both low- and high-anxious subjects (Jamner et al., 1988, p. 571). In further support of the opioid peptide hypothesis, these researchers also reported that the administration of naloxone and other opioid antagonists has been conversely associated with increases in the subjective experience of tension, anxiety, anger, and hostility; reduced joy and euphoria; and heightened affective distress in both experienced and induced pain.

While the objective of many psychotherapies is to strip away illusions, and awareness of reality is considered a prerequisite for healthy mental functioning, denial and the illusion of control may have adaptive value in many circumstances, at least in the short term (Shedler et al., 1993; Taylor, 1983; Taylor & Brown, 1988). According to Paulhus (1989), the MC scale appears to measure both propensities for self-deception and impression management, or what may be two distinct aspects of repressive coping, and self-deception measures tap "an honest, positivistic bias that contributes to good psychological adjustment" (p. 201). Thus, those who score high on "self-deceptive positivity" are for the most part "well-adjusted individuals who are biased in the sense that they are overly optimistic and play down the negative aspects of their personality" (p. 201). In studies using the bogus pipeline technique, most high scorers on the MC have been found to be self-deceivers, while a minority may be engaged in impression management, or the (mentally unhealthy) deception of others (Weinberger, 1990).

Although repressive coping in the extreme can be undesirable because of its association with higher levels of sympathetic arousal and susceptibility to unacknowledged somatic expressions of distress, in certain arenas it has been associated with optimal performance, perseverance and goal-directed behavior, self-enhancing cognitions, feelings of mastery and control, tendencies to derive meaning from even aversive experiences, and the rapid inhibition of negative affective responses to stressors (Shedler et al., 1993; Taylor & Brown, 1988; Tomarken & Davidson, 1994). All these attributes may be protective against the use of addictive agents.

It has also been argued that the repression of certain higher-order perceptions may sometimes be not only desirable, but also outright essential to emotional health and might better be labeled a talent rather than a form of pathology (Schwartz, 1990, p. 430; Schwartz & Kline, 1995). Certain types of self-control such as dis-

tancing, cognitive suppression, or the capacity to stop thinking about and distract oneself from negative events, as well as some level of “illusory optimism” have all been related to mental health and low psychological distress in general (Paez, Basabe, Valdosedá, Velasco, & Iraurgi, 1995, p. 216; Vaillant, 1990). Other types of inhibition, however, such as cognitive-behavioral avoidance, wishful thinking, and passive, stoic acceptance, have been associated with poorer outcomes and greater emotional distress in those who are physically ill (Paez et al., 1995). Some recent studies suggest that positive illusions can have both adaptive and maladaptive outcomes, depending on their longevity and context, and seem far more problematic for students than for individuals in health care settings. Thus, college students with overly inflated views of themselves (as opposed to those whose positive appraisals are based on more accurate and realistic self-judgments) may thrive in school initially but over time show decreasing levels of self-esteem and well-being, along with deteriorating performance and progressive disengagement from the academic community (Robins & Beer, 2001).

While unrealistically positive beliefs about themselves can help students regulate affect for a time, eventually, in the face of real-life standards and tests, they may be forced to confront the fact that such beliefs will not be realized—and the result can be diminished wellness and self-assessments (Robins & Beer, 2001). Drake (2001) found that undergraduates who demonstrated left hemispheric predominance, which is associated with positive affect, self-enhancing cognitions, and repressive coping styles, fared surprisingly poorly in academia, in part because they did not attend to both unpleasant self-relevant information (negative feedback about their performance) and factual information integral to a course that they may have found disagreeable or incompatible with their own beliefs.

In a treatment context, however, both during the initial stages of threat and intermittently when people must come to terms with information that is difficult to assimilate or accept, repressive or avoidant coping may be the preferred response, because it provides a psychological reprieve from the ongoing pressures of the stressful situation (Carver, Scheier, & Pozo, 1992). Thus, in some instances, avoidance is a more adaptive behavior than confrontation and may lead to more positive outcomes in the short run (Suls & Fletcher, 1985). In terms of illicit drug use, the tendency for repressive copers to have a poor memory for negative emotional experiences may protect them from the relapse that may readily overtake others who recall such episodes and feelings all too vividly. The repressive response style

may also have longer-term utility for such individuals, as the capacity to reframe reality in a direction that elevates self-esteem, maintains beliefs in personal efficacy, and encourages optimistic views of the future can serve a wide variety of cognitive, affective, and social functions (Taylor & Brown, 1988).

Clinical observations of highly intelligent, successful, and pervasively repressed teenagers and adults who coped effectively with serious mental, emotional, and/or physical abuse while growing up have confirmed that they learned how to quell loneliness, depression, anger, and fear early in life, as well as to inhibit thoughts and behaviors that might have been disruptive to their families. Such coping styles in their original settings were remarkably creative and adaptive in enabling these individuals to surmount difficult childhoods and to attain extraordinary levels of professional success. The challenge for such “masters of repression” is to assist them in relinquishing their overlearned—as well as no longer necessary, potentially self-defeating, and somatically injurious—mental strategies in favor of more flexible and demonstrably safe ones that are appropriate to their current lives (Schwartz, 1990, p. 430).

Lower than average scores on the MC scale are associated with higher than usual levels of psychological distress, as individuals who are less inclined toward repressive coping are not as given to idealized self-reports or are as inattentive to negative realities and thus are more vulnerable to depression and anxiety (Lane et al., 1990). For this reason, too little repressive coping can conceivably be a risk factor for a substance use disorder. However, such individuals may be less susceptible to strictly physical or organic expressions of distress (Lane et al., 1990; Wickramasekera, 1998).

In relationships, repressors’ rigid regulation of painful affects and their relative inability to predict or evaluate their own behavior can limit their perceptions of the nuances of others’ behavior and feelings, leading to failures of both self-assertion and empathy. The result can be a general lack of social competence in communication and deficits in “interpersonal cognitive complexity,” including the ability to grasp the implications or consequences of particular interactions (Weinberger, 1990, p. 361). As such, repressive coping may be linked with difficulties in both intra- and interpersonal aspects of emotional intelligence.

Moreover, the exchanges involved in both supportive and probing analytic therapeutic relationships may fail to benefit repressors in terms of clarifying thoughts, feelings, or values, as their tendency to externalize blame may lead them to avoid taking the (potentially threatening) internal responsibility that can facilitate

self-understanding and problem-focused coping. Thus, in maintaining their invulnerability to distress and capability of handling all issues, such people may not be as likely to seek or benefit from therapeutic interventions and thus not apt to achieve significant progress in the areas where they presumably need it most.

ALEXITHYMIA OR REPRESSIVE COPING?

In a study by Loisel and Dawson (1988), patients who scored high on the original 26-item Toronto Alexithymia Scale and low on the 10-item private self-consciousness subscale of the Self-Consciousness Scale showed not only a relatively undifferentiated emotional awareness and limited self-focused attention, as predicted, but also difficulty disclosing other self-relevant information that was *lacking* in affective content. (Just the opposite would be expected if denial or repression of affect were common among subjects in the alexithymic category.) This finding suggests that alexithymia is distinct from emotional repression in that it may be more than a disorder of emotional awareness and actually involve deficits in the organization and perception of the self as a whole (Loisel & Dawson, 1988).

Newton and Contrada (1994) studied 86 healthy female subjects categorized as low anxious, high anxious, and repressors, each of whom completed the TAS-20 and was required to deliver a stressful self-disclosing speech. The alexithymia scores of the high-anxious subjects were significantly greater than those of the repressors. The subjects' self-reported negative affect was compared with their heart-rate responses during the stressful task in order to assess their emotional responses.

Results indicated that those scoring high in alexithymia showed a pattern of emotional responding that was characteristic of highly anxious subjects (i.e., their self-report of negative affect outweighed their degree of sympathetic nervous system responsiveness in the threatening situation), while those scoring low in alexithymia exhibited a response pattern like that of repressors (their high level of sympathetic nervous system responsiveness was inconsistent with their minimization of self-reported distress). These findings suggest that while alexithymia and repression may be defined by deficiencies in affective expression, they may be quite distinct from each other, with repression resembling a relatively low degree of alexithymia, and a higher level of alexithymia appearing more like a sensitizing coping style than a repressive one (Newton & Contrada, 1994). Indeed, despite their clinical and conceptual similarities, repression and alexithymia contrast mark-

edly in several ways. To receive a high score on either the original or current alexithymia scale, it is necessary to acknowledge experiencing negative emotions such as fear, sadness, and anger even while reporting confusion about the nature of the reasons for such feelings and difficulty conveying them to others. Thus, to be labeled alexithymic, one must admit not only to having upsetting feelings, but also to a lack of control or awareness of these. It is precisely such weaknesses in the emotional arena that repressors are apparently incapable of acknowledging. Indeed, as already noted, a self-presentation of emotional well-being and emotional control is essential to the repressive coping style (Newton & Contrada, 1994; Weinberger, 1990).

Martin and Pihl (1986) found evidence of elevated levels of sympathetic activity in individuals identified as alexithymic measured during periods of both stress and relaxation. In contrast with those who scored low on alexithymia measures, the sympathetic activity of "highs" during the recovery interval remained essentially unchanged from what it had been during the stressful period, suggesting that alexithymic people do not recover adequately from stress and also lack effective ways of modulating sympathetic arousal states in response to changing environmental conditions. Also noteworthy was that the higher and more sustained patterns of stress ratings for the alexithymics along with strong evidence of dissociation between their physiological and subjective responses distinguished them not only from their non-alexithymic counterparts, but also from those identified as repressors.

As expected, the repressors showed high physiological responses to stress combined with low subjective and behavioral responses. However, the high alexithymics showed similarly high levels of stress reactivity, but these were combined with both high and dissociated levels of subjective response (Martin & Pihl, 1986). Despite such findings, Newton and Contrada (1994) caution against assuming a direct correspondence between highly stressed or anxious subjects and those high in alexithymia, or between repressors and individuals who are low in alexithymia based on presently available data.

POSSIBLE GENDER DIFFERENCES

A recent study of heroin users in an outpatient treatment setting (Fortino, 2002) found that the five personality measures together accounted for nearly 46% of the variance in scores for abstinence from illicit drug use among the men, a figure that dropped to less than

22% among the women with regard to the same outcome variable. Whereas for both the men and women in this study, the five personality measures accounted for approximately the same degree of variance (30%) in overall treatment outcome scores, in women, the personality dimensions accounted for considerably more of the variance in interpersonal competence as opposed to the variance in abstinence from illicit drug use (30% vs. 5%), which was just the opposite of the trend seen in men. One noteworthy finding was that in women, only alexithymia correlated negatively with abstinence from illicit drug use. Moreover, in women, but not in men, absorption figured as a positive contributor to treatment success as well as to interpersonal competence, whereas repressive coping, which was positively correlated with abstinence in men, showed no significant correlation in women with either abstinence or interpersonal factors. Perhaps most strikingly, in contrast to men, negative affect in women did not contribute significantly, for better or worse, to overall success in treatment, abstinence per se, or competence in interpersonal contexts.

The higher incidence of alexithymia in men may account for why they have been widely reported to show more antisocial acting-out behaviors as a means of coping while in treatment settings, along with tendencies to externalize blame and block out or minimize feelings of vulnerability. By contrast, women have presented with more overtly depressed, helpless, and worthless feelings and have been inclined to look more inwardly for the source of their problems (Lex, 1993; Reed, 1987). Much of the relatively scant literature on women and addiction has emphasized that they are more psychologically distressed than their male counterparts, with more self-reported and severe emotional complaints such as depression, anxiety, and feelings of guilt (Dahlgren & Willander, 1989; Lex, 1993; Prather & Fidell, 1978; Reed, 1987). Some of the earlier research has been criticized on methodological grounds and for viewing deviations from female stereotypes or normal standards for males as necessarily pathological (Marsh, Colten, & Tucker, 1982; Marsh & Miller, 1985).

A recent review found that 7 out of the 10 most relevant studies from a total of the only 12 existing between 1980 and 1997 that addressed gender differences in samples of clients who were maintained on methadone, the most common treatment modality for heroin addiction, reported that women suffered from more mental health problems and reported less satisfaction with their emotional status (Chatham, Hiller, Rowan-Szal, Joe, & Simpson, 1999). Two of the studies also disclosed a higher incidence of sexual abuse in early childhood among women than among men. If this

finding is typical, it may help account for the higher scores in absorption among the women in this study, as certain aspects of absorption such as fantasy proneness and tendencies toward dissociation have been associated with childhood abuse (Lynn & Rhue, 1988; Rhue & Lynn, 1987). In their own research on interview data at admission to treatment and during a 1-year follow-up, Chatham et al. (1999) similarly found that women described more dysfunctional and abusive families of origin, were more likely to report using drugs to alleviate psychological distress, and also cited a higher incidence of physical health symptoms. In addition, a significantly larger percentage sought treatment for emotional difficulties over a 6-month period and showed greater willingness to pursue professional help after leaving a treatment facility, a finding congruent with that of other researchers.

If women indeed show greater tendencies than men toward negative affect, absorption, and self-consciousness and are less likely to be alexithymic, it is not surprising that they would be more vocal than men about their emotional states. The study by Chatham et al. (1999) of more physical complaints may also correspond with this author's finding of significantly higher scores on repressive coping among female heroin users, a personality style associated with an inclination to somatize emotional distress. However, women may often be "failed repressors," or defensive, highly anxious which leaves them subject to both physical and psychological symptoms, possibly to a greater degree than their male counterparts.

Despite their disproportionate difficulties upon entering programs, women appear to benefit from treatment more than do men in the areas of family functioning and psychosocial status, which have been cited as instrumental factors in initiating their addictive drug use (Chatham et al., 1999). As already noted, prior research has concurred that compared to men, addicted women have a higher reported prevalence of anxiety, depression, low self-worth, and family dysfunction. This study in part corroborates these earlier findings, as the women scored significantly higher than the men on negative affect, which is an index of their susceptibility to aversive mood states, ruminative styles of coping, and unfavorable self-perceptions. But they also scored higher on absorption, which is associated with a readiness for affective engagement and imaginal activity, and higher on self-consciousness, which may facilitate introspection, all potential means of regulating painful affect as well as possible contributors to more intense or substantive involvement in any treatment setting. Such personality variables can facilitate interpersonal

relatedness and be viewed as potential strengths that have been overlooked in previous studies emphasizing the more pathological aspects of women's addiction.

Indeed, women substance users have been found to be "optimally responsive to social relationships," including peer support from other women, and more concerned about these attachments than men (Bartholomew, Rowan-Szal, Chatham, & Simpson, 1994; Reed, 1987, p. 157). Moreover, both abstinence and continued drug use in women have been shown to be influenced substantially by family members and intimate others (Marsh & Miller, 1985).

Although it has already been observed that absorption and self-consciousness in the context of high negative affect can be problematic because they foster tendencies to catastrophize or magnify distress, these same personality variables may be assets in a therapeutic setting where interpersonal support is available and emotional expression is valued and encouraged. While women typically present with more emotional issues at the outset, their apparently greater vulnerability may not translate into risk factors during treatment, as they may also have other ways of modulating negative mood states and managing difficult circumstances that are not tapped to the same extent by men. These mood regulators include their affiliations—or attempted reconciliations—with family members and friends, as well as their affinity for the mental health professionals in treatment programs, with whom they are reportedly more engaged and communicative than are men (Chatham et al., 1999; Rowan-Szal, Chatham, Joe, & Simpson, 2000). This suggests that while personality variables are still important contributors to recovery in women, once a commitment to treatment has been made, the way such variables relate to their success or failure in utilizing the interpersonal aspects of the treatment process (i.e., of cultivating various relationships as sources of support and coping) may be more directly instrumental to the final outcome.

That women give more affiliative and biopsychological reasons for their initial as well as ongoing heroin use while men tend to view it in more physiological terms (Binion, 1982) may be explained largely by the personality variables explored in this study. The men's higher scores on alexithymia and lower scores on absorption and self-consciousness may be indicative of a more concrete cognitive style, which would lead them to attribute difficulties or problems, addiction included, to physical rather than emotional or interpersonal origins. In Binion's (1982) study, when asked about the reasons they used drugs, many of the men mentioned that heroin helped them relax in social situations, which may have been a covert or sex-stereotyped way

of speaking about their anxiety without directly divulging their emotional state.

One study found that heroin-addicted women as a group are more field dependent than normal controls, as well as significantly more field dependent than their male counterparts, who appeared similar in this measure to normal males. Both field-dependent and field-independent cognitive styles have been associated with specific constellations of personality characteristics (Arnon, Kleinman, & Kissin, 1974). For example, field dependence is correlated with responsiveness to social cues and dependence on one's surroundings for structure and support, as well as with a defensive or repressive coping style. By contrast, field independence is associated with the separation of self from environment, a more analytic cognitive style, and the use of defenses based on isolation and intellectualization (Arnon et al., 1974; Galin, 1974). As already noted, the women in a personality-based study of heroin users outscored their male counterparts on repressive and defensive coping and also were lower on scores for alexithymia, which is associated with an emotionally distant communicative style as well as less secure patterns of interpersonal attachment. To the extent that absorption denotes capacities for affective involvement and suggestibility or responsivity to influences in one's surroundings, the women in this study might share some traits of field dependency with those in the earlier research, and in somewhat parallel contrast with the men as well. The already observed relative prominence of interpersonal factors for women compared with personality variables with regard to outcomes itself suggests a greater reliance on others in their environment for the kind of support that can contribute to success in treatment.

Galin (1974) notes that field dependence reflects the more pathological and primitive and less desirable end of the psychological spectrum, not because it is a relatively unhealthy tendency per se, but rather simply because all field-dependent tests have been set up to require the subject to be as field independent as possible; none ask the individual to be optimally responsive to the context. Accordingly, these tests can disclose only an ability to perform "in a field-independent mode on demand, not the relative ability to operate in either mode, or the preference for one mode over the other" (Galin, 1974, p. 580).

In summary, it appears that while women are ostensibly more distressed than men, they may also be more attuned to and expressive of these feelings in a social context as well as mindful of the need to manage them. This may explain both why they initially come to depend on drugs after being introduced to them, typically by a male partner, and why, once they decide to seek

help, they subsequently approach treatment in a more intense, in-depth, and/or interpersonally connected way (Eldred & Washington, 1976; Marsh & Miller, 1985.). If, as Binion (1982) observes, drug use among women is ultimately more reactive to family situations and interpersonal relationships, any measurable progress they achieve in these areas may indeed have a more significant impact on outcome than the particular configuration of personality traits that they bring into treatment.

It seems counterintuitive that personality measures would be more relevant with respect to abstinence or drug-related outcomes for the men than women since many of the former are reported to have been initiated into drug use by adolescent peer pressure and to indulge for social/recreational reasons rather than to have been motivated at the outset primarily by a desire to regulate some internal mood state, as has been considered characteristic of women (Chatham et al., 1999; Reed, 1987). Of course, earlier literature on the social conformist pressures attending chemical dependence in males may not reflect recent sociodemographic changes that can possibly point to comparable pressures for adolescent women, thereby blurring the traditional distinction between the sexes regarding the factors that contribute to the initial impetus for addictive drug use. Thus, the so-called social milieu surrounding heroin use may no longer vary much, if at all, as a function of sex, as was reported over 30 years ago (Carter & McNair, 1994; Eldred & Washington, 1976). Moreover, if it is also true that women are frequently induced to use illicit drugs by a male companion or family member (Lex, 1993), this suggests that they are just as compelled as men by an outside influence except that in their case, the extrinsic pressure stems from a single individual rather than a peer group (Binion, 1982; Eldred & Washington, 1976; Marsh & Miller, 1985).

It should be noted, however, that whatever influences may lead to the *initiation* of drug use in either women or men do not necessarily have any relevance to the reasons individuals proceed to develop a chronic addiction or even more pertinently to how well they ultimately fare in treatment. Thus, personality variables can conceivably be associated in a significant way with an individual's experience and degree of success in addiction treatment regardless of how he or she was originally introduced to habitual drug use.

SUBSTANCE USE AND CEREBRAL LATERALITY

It has been observed that the right and left cerebral hemispheres play different yet complementary roles

in mediating a wide variety of behaviors and mental processes. Moreover, as already noted, associations have been made separately for alexithymia, absorption, negative affect, and repressive coping with the functions of—or possible dissociations between—both hemispheres. The right hemisphere is considered to be involved primarily in the processing and regulation of negative (withdrawal-related) emotions, whereas positive and social (approach-oriented) emotions are believed to be mediated predominantly by the left hemisphere (Fox & Davidson, 1984; Sackeim, Greenberg, Weiman, Gur, Hungerbuhler, & Geschwind, 1982; Taylor et al., 1997). Theorists who have sought to integrate specialized functions of the two cerebral hemispheres with subcortical mechanisms in the processing of emotion have also suggested that the right hemisphere is involved preferentially in emotional arousal, whereas the left hemisphere is involved in the inhibition and control of emotional expression (Taylor et al., 1997, p. 103).

The direction and magnitude of the error on a standard visual (horizontal) line-bisecting task indicates a relative predominance of activation in the opposing (contralateral) cerebral hemisphere. Thus, individuals who make mostly rightward errors (repeatedly bisect lines to the right of their true center) show a relative left-hemisphere predominance, whereas those who consistently divide the lines to the left of their true center show right-hemisphere predominance (Drake & Myers, 2000; Drake & Ulrich, 1992). In contrast to certain neurologically impaired individuals, the majority of neurologically intact persons tend to divide lines to the left of the true center (leftward bisecting errors) when asked to divide a horizontal line in half (Drake & Ulrich, 1992).

Leftward line bisecting by normal individuals is referred to as “pseudo neglect” to distinguish it from the rightward hemispatial neglect shown by impaired patients, a phenomenon first documented in the 1940s. In either case, “neglect” is considered a consequence of brain asymmetries in the allocation of spatial attention (Drake & Ulrich, 1992; Jewell & McCourt, 2000). A variety of methods involving the bisection of a series of horizontal or vertical lines have been used to assess pseudo neglect in neurologically intact individuals. The direction and magnitude of deviations from the true center of each line are calculated to arrive at a total score for errors in line bisecting (Jewell & McCourt, 2000). Among the methods used to determine this score, the paradigm developed by Drake is considered a reliable measure of relative brain hemispheric predominance.

While much of the extensive research on pseudo neglect has addressed fairly technical issues, a few investigators have studied this phenomenon in terms of

specific personality variables and individual differences. For example, a trend toward an increased incidence of rightward errors among older individuals compared with those identified as young and middle aged has been observed. Such a finding could be a consequence of age-related changes in the organization of cerebral functions involved with attention (Jewell & McCourt, 2000). It has also been reported that an individual's level of personal optimism, risk taking, and positive affect may be predicted based on the magnitude of rightward errors on the line-bisecting task (Drake & Myers, 2000; Drake & Ulrich, 1992). The association between rightward errors and positive affect corresponds with previous electrophysiological EEG studies that have found correlations between left-hemispheric activation, or predominance, and positive affect (Tomarken & Davidson, 1994). By contrast, right-frontal activation has been linked with neuroticism, depression, negative cognitions, and reduced tolerance for pain (Pauli, Wiedemann, & Nickola, 1999).

Whether these observations apply to individuals in treatment for addictive drug use remains an open question. A recent study of heroin users participating in outpatient treatment found that the vast majority of those who were right handed made often pronounced rightward errors indicative of left-hemispheric activation, or predominance—contrary to expectations for this population. Indeed, the reason for this is that left-hemispheric activation has been associated not only with positive affect, as already noted, but also with self-enhancing cognitions along with feelings of mastery, strength, and dominance, among other favorable characteristics that one would not intuitively connect with propensities to chemical dependence. Such a finding suggests the possibility that heroin-dependent people in treatment may have a cortical organization and/or neurophysiological response system that differs from those of individuals who have never been dependent on drugs and/or from those of heroin-dependent individuals who are not in treatment.

Although it seems counterintuitive that a population of individuals in treatment for chronic heroin use would necessarily be dominant in the aforementioned positive traits, receiving and responding to treatment itself may represent an uplifting and powerful life event that could elicit a state of positive emotionality and thereby possibly account for the rightward trend in bisecting among this group. In contrast with the findings of predominantly rightward errors among athletes (Carlstedt, 2001), extraversion, the trait that comes closest to assessing levels of optimism, risk taking, and positive affect and that is also measured by the Eysenck Per-

sonality Inventory, was not correlated with this population's line-bisecting scores, nor was repressive coping, another stable personality dimension associated with a positive cognitive/affective bias. Thus, line bisecting did not appear to be measuring a trait-like tendency among the participants in this study.

Nonetheless, the number of rightward errors among the participants in this study paralleled and even surpassed that of a group of elite athletes (Carlstedt, 2001). One possible explanation for the similar prevalence of left-hemispheric predominance in these otherwise seemingly disparate populations is that the constant repetition associated with achieving a high level of skill may lead to permanent changes in the brain, and left-hemispheric activation may develop as a function of some forms of learning (Carlstedt, 2001). Chemically dependent individuals are by definition well practiced and highly skilled at their particular lifestyle, obsessively engaged in their specialized activities, and have typically repeated and mastered them over many years. A concomitant of well-entrenched learning, perseverance or resistance to change may also be considered characteristic of those who are battling an addiction to heroin use or any other activity, which may explain why treatment itself must be sustained, comprehensive, and repetitive to be ultimately successful. Exploring the prevalence of leftward or rightward errors on the line-bisecting task may help determine whether the cortical function and/or organization of heroin users differ from those of non-users, and, if so, what such differences imply in terms of personality factors and optimal approaches to treatment.

RISK AND PROTECTIVE FACTORS: TREATMENT IMPLICATIONS

As we have seen, the personality dimensions of alexithymia, negative affect, absorption, private self-consciousness, and repressive coping in chemically dependent individuals are worthy of investigation given their association with distinctive cognitive and affective tendencies that may predispose to or possibly protect against the use of addictive drugs in many individuals. If the personality variables can be considered indicative of some crucial deficit or strength in affect regulation, then it might be expected that a disproportionate number of substance users who do well in a treatment setting will show evidence of distinctive patterns of these dimensions compared to those who fare poorly. (It is also possible that substance users and non-users will demonstrate different groupings of such traits alto-

gether, along with differences in cerebral laterality as well.) Identifying these tendencies may influence and refine the way these individuals are managed therapeutically to maximize their engagement in the recovery process, promote favorable responses to treatment, and enhance their ability to negotiate significant intimate and social relationships that are critical to maintaining long-term abstinence.

It should be noted that while the emphasis in this chapter was on difficulties in the perception, cognitive processing, communication, and regulation of affect, these represent only a few of the multiple risk factors and antecedents for drug dependence. Besides personality-related and neurophysiological susceptibilities, some of the most salient associated factors are demographic and socioeconomic status, family discord, weak religious/cultural affiliations, isolation from the value-shaping influences of community and social institutions, identification with a non-normative peer group, a family history of alcohol or drug use, and easy access to alcohol and drugs. No single factor appears to account for the genesis of an addiction, but rather it is the aggregate of these, along with inherent vulnerabilities, that seem critical in explaining risk (Tarter, 1988).

Yet while the etiology of substance use disorders is obviously multifaceted, it may still be possible to identify patterns in the cognitive and affective styles of many chemically dependent individuals that can illuminate the reasons for their susceptibility and have significant implications for their success in treatment as well. Indeed, a personality-based model might be viewed as a starting point for assessments that can be further amplified by considerations of situational issues such as family, peer group, socioeconomic, and cultural influences, among others. Moreover, although this chapter has been exclusively centered on substance use, the possibility that such a model can also be applied to other addictive behaviors such as gambling and overeating is certainly conceivable and worthy of further investigation. Based on the preceding review, repressive coping, absorption, and private self-consciousness can be viewed as so-called good personality factors, whereas alexithymia and negative affect are unfavorable in terms of both abstinence from illicit drug use and quality of interpersonal relationships.

As observed, the verbal inhibition of aversive feelings characteristic of alexithymia is associated with higher levels of physiological arousal and somatic complaints along with behaviors such as substance use or overfeeding that indirectly convey and generally mismanage this poorly articulated distress. Alexithymic individuals are not readily able to alter states of con-

sciousness to encourage self-soothing; are relatively unaware of psychological distress, often mistaking this for a physical disturbance; and thus are all too apt to resort to an externalized means of combating the unwanted symptom. Negative affect is problematic because it denotes tendencies to experience and dwell on painful feelings even in the absence of apparent stressors, contributing to the potential for self-medication with illicit drugs. Both alexithymia and negative affect are associated with a relative inability to reset dysfunctional feedback systems when original stressors are reduced (Taylor et al., 1997; Wickramasekera, 1988).

It is now known that addictive drugs in general, and specifically the short-acting opioids such as heroin, may lead to profound molecular and neurochemical changes, which can alter physiologic functions; with chronic exposure, these alterations may be persistent or even permanent (Stimmel & Kreek, 2000). One of the most critical of these changes involves a hyper-responsivity to stress at a biochemical and ultimately behavioral level that can make individuals susceptible to relapse over a lifetime unless adaptive, non-automatic coping skills and cognitive patterns are repeatedly practiced and reinforced, which is the aim of most good therapy (Stimmel & Kreek, 2000; Tiffany, 1990). While long-term methadone use has also been shown to contribute to the normalization of such stress responsivity via the hypothalamic-adrenal-pituitary axis (Stimmel & Kreek, 2000), this synthetic, long-acting opioid alone may be inadequate if not integrated with appropriate cognitive and behavioral changes that are achieved over time through therapeutic interactions with clinicians in individual and group settings. Those who are high in alexithymia or low in absorption, and thus are less given to verbalizing emotions openly as well as more instrumental in their treatment goals, may not be very receptive to “talking” therapies (Wickramasekera, 1988). However, although the problems commonly associated with alexithymia—inadequate verbalization of feelings, impoverished imagination, scarcity of dreams, and the inability to distinguish among emotional states—can create serious obstacles to the effectiveness or appropriateness of traditional psychotherapies, it may be possible to modify certain therapeutic techniques to enhance their benefit in such cases (Krystal, 1979).

One of the first tasks for a clinician confronting alexithymia may be to assist such individuals in identifying the links between their feelings and various physical states, and the emotional significance of certain bodily responses. Training alexithymics to observe their inner states and to become more aware of the physiological nature of their distress can help them understand their

body's "language" as the well-camouflaged medium through which they communicate and express emotion (Krystal, 1979; Lynch, 1985). One possible way to facilitate such understanding may be through the use of bio-feedback instruments. These can track the physiological correlates of psychological changes and thus place the body's "inside information" on the outside in observable, concrete, and quantifiable terms that are readily accessible—and convincing—to such literal-minded individuals (Wickramasekera, 1988).

Another objective is to assist such individuals in acquiring more affect tolerance; thus, they need to reacquaint themselves with their emotions as useful, informative signals rather than as dreaded forces that threaten to overwhelm them. Alexithymics who develop dependencies on illicit drugs and have explosive but fleeting rage reactions may have learned early on that such displays of emotion are their most effective way of communicating with and controlling others (Krystal, 1979). The faulty cognitions that perpetuate such maladaptive patterns have to be discovered and interpreted before these individuals can learn gradually to verbalize their emotions. Reconstructing the cognitive elements of unvoiced feelings and identifying the narrative behind them or the meanings they express can help in interpreting, organizing, and recognizing emotions so that they can literally be put into words (Krystal, 1979). It is also possible that therapies emphasizing social skills training and interpersonal problem solving may be effective for such individuals. In addition, they may benefit from focusing on particular issues such as anger management, or starting out with gender-specific groups, which can foster communication on a relatively concrete or thematic level, before moving on to more probing, in-depth emotional exchanges in other settings.

While it can be said that alexithymia and negative affect are detrimental to emotional self-regulation, absorption, self-consciousness, and repressive coping may facilitate the modulation of painful affect and thus have potential value for mental and emotional health. Specifically, absorption may be associated with capacities for self-soothing, imaginative and affective engagement, the strength of the placebo effect, positive attentional shifts, creativity, pain management, and even intrinsic religiosity or spiritual pursuits (Levin et al., 1998; Wickramasekera, 1999). All of these may counter aversive emotional states and thus render individuals less vulnerable to the solace provided by external agents, including illicit drugs. Private self-consciousness can facilitate introspection or at least readiness to address internal states and thus can be a significant starting

point in self-exploratory psychotherapies. Repressive coping has already been shown in previous literature to be associated with a lower likelihood of substance use (Weinberger, 1990), higher tolerance for pain and distress, self-enhancing cognitions, rapid inhibition of negative responses to stress and accentuation of positive affects, goal-directed behaviors, feelings of mastery, and tendencies to derive meaning from even the most difficult situations (Shedler et al., 1993; Taylor & Brown, 1988; Tomarken & Davidson, 1994). Indeed, the repression of negative affect and the illusion of maintaining control may have decided adaptive value in many circumstances when situations are otherwise unalterable. It is important, however, to distinguish among different forms of repressive coping with respect to the enhancement of mental health and the regulation of psychological distress. Thus, active distancing, thought stopping, cognitive suppression, and self-deceptive positivity or global illusory optimism have been associated with affective well-being and adjustment, whereas stoic acceptance, wishful thinking, and cognitive/behavioral avoidance—each suggestive of passive, resigned, or fearful and inhibited means of coping—have been associated with unfavorable outcomes (Paez et al, 1995).

If private self-consciousness is associated with tendencies toward introspection and absorption is related to affective engagement as well as a potential repertoire of coping and self-regulating strategies (Chassin, Mann, & Sher, 1988), those who are high in one or both of these personality dimensions may be good candidates for therapies that stress awareness of feeling states, self-soothing, and mind/body healing, including approaches that involve creative and imaginal activities. In addition, keeping a written journal of dreams or fantasies and any form of experiential therapy involving art, music, dance, or other media may especially resonate with such individuals. For those who have difficulty in the verbal sphere, of course, these other outlets for personal and affective expression may facilitate more authentic communication as well.

Differences in levels of alexithymia and absorption capacity may account for why the same therapies or approaches may be effective for different reasons. Thus, an individual with a primarily concrete thinking style might be drawn to Narcotics or Alcoholics Anonymous because of these organizations' focus on 12 specific, identifiable steps and may find guidance in the hierarchical arrangement of these goals, while someone with a more absorbed, affect-laden style might be more responsive to NA or AA's invocation of a higher power, or to spirituality in general as a source of healing and recovery.

For those whose early attachments with caregivers were less than satisfactory, it is possible that participating in a group that provides nurturing support, unconditional acceptance, good modeling, affirmation, empathic responses, and opportunities for idealization (of those who do well and remain clean) can help repair the here-and-now relationships these individuals have with caring others and thus assist them in regulating affect (Bell & Khantzian, 1991).

Regardless of a client's personality profile, coercive or confrontational counseling styles that have traditionally been deployed in some treatment settings to break down defenses and tendencies to avoid or externalize responsibility would likely be inappropriate for anyone who is already feeling blameworthy, hopeless, and depressed. Approaches emphasizing competence, positive self-regard, and strength rather than personal pathology or powerlessness over substance use would be decidedly more relevant for these individuals.

In addition, it should be noted that all the personality dimensions featured in this study, even the ones found to be relatively detrimental for maintaining abstinence, are best viewed not simply as evidence of deficits or pathology. Rather, they can be seen as characteristic of how different individuals have learned to respond to both chronic stressors and day-to-day difficulties and thus can be the basis for positively oriented, client-centered interventions. For example, as previously observed, alexithymia, absorption, or repressive coping in response to severe trauma early or later in life can have decided adaptive value. Negative affect is associated with ruminative and hypervigilant cognitions that can certainly exacerbate existing problems, but it can also prompt communication of distress to others and initiate care-seeking behaviors. A high degree of private self-consciousness may also be a powerful internal motivator for engaging in life-changing, in-depth treatment.

Ultimately, a comprehensive, well-integrated, personality-based approach holds promise as a means of identifying individuals at risk as well as those with particular capabilities or prospects for favorable responses to care. But beyond whatever descriptive or even predictive value this perspective may have, perhaps the chief benefit of assessing strengths and susceptibilities in the domain of affect regulation and emotional intelligence through relevant personality variables is that the latter can be apprehended through valid and reliable forms of measurement and subsequent analysis while helping clinicians design therapeutic approaches with the greatest likelihood for success in particular individuals. It is hoped that awareness of such affect- and personality-related differences in care seekers can heighten the sen-

sitivity of those administering treatment to the potential benefits that may derive from exploration of these and similar variables in clinical settings.

Affective Disorders: Bridging the Gap Between Efficacy and Practice

Hunna J. Watson
Peter M. McEvoy
Laura M. Smith
Lisa M. Saulsman
Bruce N. C. Campbell
Paula R. Nathan

The 20th century witnessed impressive scientific advancements in the treatment of psychiatric conditions, particularly for the affective disorders. Empirically supported treatments for unipolar major depression and bipolar disorder were developed, and these treatments were based on convincing biological and psychological theoretical foundations. The development of these treatments has represented an important milestone in psychiatric research, and the prognosis of these conditions has greatly improved as a result.

A wide variety of disciplines are associated with cutting-edge research in affective disorder treatment. These include, but are not limited to, biomedical science, behavioral science, clinical psychology, psychiatry, nutritional medicine, neuroscience, and pharmacology. Research progresses rapidly and disparately, yet a constancy that unifies all fields is the application of the scientific method. Strict criteria for interpreting the efficacy of a treatment have helped us to separate help-

ful treatments from unhelpful treatments. Efficacy trials index optimal outcome, utilizing idealized, controlled conditions to estimate the maximum potential benefit derivable from a treatment. Sometimes the quantity of research can be difficult for clinicians to navigate, and it may appear challenging to stay abreast of the latest field or laboratory developments.

The importance of effectiveness research in the treatment of affective disorders deserves mention. Effectiveness research differs from efficacy research in that it seeks to establish whether efficacy protocols derived from laboratory settings can be successfully transported to the wider clinical settings to which individuals present for treatment. Individuals and treatment delivery in laboratory settings differ in systematic ways from naturalistic settings, usually resulting in attenuation of treatment effect in the naturalistic setting. Efficacy trials routinely exclude patients with specific accompanying psychiatric comorbidity, medical comorbidity,

personality pathology, drug or alcohol abuse history, severe suicidal ideation, or even a previous failed trial of a treatment. Individuals who present for treatment in naturalistic settings have more complex clinical presentations than those recruited in randomized, controlled trials (RCTs). Efficacy trials are conducted and implemented by experts who administer the treatment under standardized conditions with strict protocol adherence. This differs from clinical practice, whereby treatment is idiographic and follows a case formulation approach, and practice elements are implemented with greater flexibility and selectiveness. There is also pressure for clinical settings to deliver outcomes in a short time frame (Persons, Roberts, Zalecki, & Brechwald, 2006). Depression treatment protocols advocate 12–20 sessions, yet this may not be realistic or necessary. Some individuals respond quickly to treatment and the course may be tapered, whereas others may not show any initial response. Non-response after 3–4 sessions is predictive of overall non-response to CBT for depression (Ilardi & Craighead, 1994). These differences in patient and treatment characteristics between research and clinical settings make the process of benchmarking outcomes in clinical community settings invaluable, so it is important for clinicians to also attend to the findings of effectiveness trials as they become available. These studies enable us to view how more flexible adaptations of efficacy-based protocols perform in real-world settings, and they are a bottom-up strategy with which to reciprocally inform scientists of the types of adaptations and innovations required in service settings.

In this chapter we provide a contemporary review of unipolar major depression and bipolar disorder. We attend to diagnostic nosology, assessment, and illness causes and theoretical models, and we identify evidence-based treatments. There is a well-known documented gap or time lag that exists in the period between the “discovery” of a treatment and the uptake and routine implementation of that treatment in health settings (Cabana, Rand, Powe, Wu, Wilson, Abboud, & Rubin, 1999; Lang, Wyer, & Haynes, 2007). This gap can occur for many reasons, both macro (relating to ethical, legal, or health care systems and organizations) and micro (relating to the specific setting, service, or clinician) in origin. One of our key goals is to encourage and facilitate the transportability and integration of efficacious treatments to service settings. We provide treatment plans for two case studies and outline networks and resources that are likely to be helpful to patients and their families, clinicians working with patients, professionals who want to develop their knowledge of treatment methods, and researchers. Although

when discussing cases, we necessarily adhere closely to our clinical specialty (i.e., clinical psychology) and field of expertise (i.e., cognitive-behavioral therapy), this is not to the denouncement of other suitable treatment approaches. We advocate the use of biologically based and psychologically based interventions, implemented in accordance with evidence-based research and clinical practice guidelines. Ultimately we hope that illustrating how we bridge the gap between efficacy research and clinical practice in our own service setting will assist other clinicians to bridge the gap within their own treatment context and offer researchers insight into the innovations necessary to improve treatment transport to clinical settings, which is particularly relevant in the present age of managed care.

EPIDEMIOLOGY

The epidemiology of affective disorders has been well established. Unipolar major depressive disorder is twice as common in women as men, with a lifetime prevalence of 10%–25% for women and 5%–12% for men, and a current prevalence of around 5%–9% for women and 2%–3% for men (American Psychiatric Association, 2000b). Bipolar disorder has a lifetime prevalence between .4% and 3.9% and a 1-month prevalence of .6% (Bijl, Ravelli, & van Zessen, 1998; Jacobi, Wittchen, Höltling, Höfler, Pfister, Müller, & Lieb, 2004; Kessler, Berglund, Demler, Jin, & Walters, 2005; Kessler, Rubinow, Holmes, Abelson, & Zhao 1997; Merikangas, Hagop, Angst, Greenberg, Hirschfield, Petukhova, & Kessler, 2007). Bipolar I disorder is more common than bipolar II disorder.

The average age of onset for major depression is between 30 and 40 years, compared to the early 20s for bipolar disorder. Earlier onset of affective disorders (before age 21) is associated with greater chronicity, poorer prognosis, greater contribution of genetics, and lesser contribution of psychosocial factors. Although clinicians speak of an acute episode of depression or bipolar disorder, affective disorders are chronic, lifelong illnesses with a high risk for relapse and/or recurrence (Berti Ceroni, Neri, & Pezzoli, 1984; Keller, Lavori, Lewis, & Klerman, 1983). About half of those identified as depressed are not recovered when reassessed at 6 months, and 2- to 20-year prospective follow-up studies show that 5%–27% of individuals experiencing a first episode of depression remain chronically ill (Dubovsky, Brooks, & Dobovsky, 2002; Lee & Murray, 1988). Nearly all those who experience a single manic episode will have future episodes (American Psychiatric Associa-

tion, 2000b). A lifelong follow-up study of 219 patients with bipolar disorder (median age of 68) showed that 16% recovered, 8% achieved partial remission, 52% experienced recurrent episodes, 16% were chronically ill, and 8% committed suicide (Angst & Sellaro, 2000). Lifetime rates of suicide attempts are greater in bipolar disorder than in depression, and both are heightened relative to the general population (Mitchell, Slade, & Andrews, 2004).

The World Health Organization ranks depression as the leading cause of disability worldwide and as the fourth-leading contributor to the global burden of disease, projected to rise to second place by 2020 (Murray & Lopez, 1996). Bipolar disorder is the seventh-leading cause of disability worldwide. Depressive episodes of bipolar disorder tend to be equal to or more psychosocially debilitating than manic or hypomanic episodes (Judd et al., 2005). Concurrent psychiatric disorders occur frequently with affective disorders, particularly anxiety disorders and substance abuse. The National Comorbidity Survey showed that 59% of individuals with depression in the previous 12 months and 100% of individuals with bipolar I disorder had a comorbid Axis I disorder (Kessler, 1999).

DIAGNOSIS AND ASSESSMENT

Diagnostic Criteria

The high prevalence and serious consequences of affective disorders underscore the need for a reliable diagnostic nosology. Diagnostic criteria for depression and bipolar disorder are outlined in the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)* (American Psychiatric Association, 2000a) and the World Health Organization's (1992) *International Statistical Classification of Diseases and Related Health Problems (ICD-10)*. The diagnostic criteria are summarized in Table 12.1. There are some differences between the two systems that warrant consideration. In the *ICD-10*, separate diagnostic thresholds are used to establish mild, moderate, and severe depressive episodes. In contrast, the *DSM-IV-TR* does not categorize separate depressive episodes based on severity but uses specifiers assigned after the depressive criteria are met. The *DSM-IV-TR* does not assign a diagnosis of depression if the presenting symptoms can be accounted for by bereavement, whereas the *ICD-10* includes these cases in its diagnosis of depression.

When considering bipolar disorder, the *DSM-IV-TR* distinguishes two types (bipolar I and bipolar II) based

on whether or not the person has a history of mania or mixed episodes. Although bipolar II disorder is sometimes mistaken as a less severe form of bipolar disorder (due to the exclusion of manic episodes from diagnostic criteria), it is a severe pathology and may even be associated with a greater frequency of episodes, comorbidity, suicidal behavior, and rapid cycling than bipolar I disorder (Vieta, Reinares, & Bourgeois, 2005). The *DSM-IV-TR* introduced the "rapid cycling" specifier to describe a bipolar I or bipolar II mood disorder in which four or more episodes of depression and/or mania occur per year.

Differential diagnosis is important to determine the primary presentation. Those with unipolar and bipolar depression can present with significant anxiety, and bipolar disorder can be similar in presentation to attention-deficit/hyperactivity disorder, substance abuse, schizophrenia, schizoaffective disorder, and Axis II personality disorders (e.g., antisocial, histrionic, borderline). The treatments indicated for differential conditions vary considerably, and misapplication can have adverse consequences. For example, patients with undiagnosed bipolar disorder presenting with depression symptoms are often mistakenly assigned a diagnosis of unipolar depression (Manning, 2003). This is problematic given that an empirically supported treatment for unipolar depression is antidepressant monotherapy, yet this can trigger mania and induce cycling in bipolar patients.

Diagnostic Interviews

The Structured Clinical Interview for *DSM-IV* (SCID-IV; First, Spitzer, Gibbon, & Williams, 1997) is a well-validated diagnostic interview that assesses the greatest breadth of *DSM-IV* Axis I disorders (51 in total) relative to any other instrument. Validation studies primarily performed on earlier versions of the interview have suggested good interrater reliability overall and fair to good test-retest reliability in patient samples, but poor test-retest reliability among nonpatients. A strength of the SCID-IV is the strong parallel to current diagnostic nomenclature. Administration time is 1–3 hours.

The Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978) was developed to diagnose mood and psychotic disorders. Although it covers a smaller range of disorders than the SCID-IV, it affords greater depth of coverage. The SADS has excellent interrater and test-retest reliability for specific diagnostic categories and takes 1–2 hours to administer. Both the SADS and the SCID-IV assess current and lifetime diagnoses.

(continued)

12.1

Diagnostic Criteria for Major Depression and Bipolar Disorder from the *DSM-IV-TR* and the *ICD-10* (continued)**DSM-IV-TR DIAGNOSTIC CRITERIA FOR A BIPOLAR AFFECTIVE DISORDER****ICD-10 DIAGNOSTIC CRITERIA FOR BIPOLAR AFFECTIVE DISORDER**

3. At least 3 of the following symptoms for 4 days for hypomania or 1 week for mania (unless severe enough for hospital admission):
 - Decreased need for sleep
 - Increased activity or restlessness
 - Increased talkativeness
 - Distractibility
 - Excessive involvement in pleasurable activities that have a high potential for painful consequences
 - Flight of ideas or the subjective experience that thoughts are racing
 - Inflated self-esteem or grandiosity
4. Depressive episode (as described above)
5. Symptoms are not due to a general medical condition or the direct physiological effects of a substance.
6. Symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

- At least 3 of the following symptoms for hypomania:
- Decreased need for sleep
 - Increased activity or restlessness
 - Increased talkativeness
 - Distractibility
 - Mild overspending, or other types of reckless or irresponsible behavior
 - Increased sociability or overfamiliarity
 - Increased sexual energy

- At least 3 of the following symptoms for mania:
- Decreased need for sleep
 - Increased activity or restlessness
 - Increased talkativeness
 - Distractibility
 - Excessive involvement in pleasurable activities that have a high potential for painful consequences
 - Flight of ideas or the subjective experience that thoughts are racing
 - Inflated self-esteem or grandiosity
 - Loss of social inhibitions
 - Increased sexual energy

From *Diagnostic and Statistical Manual of Mental Disorders* (4th ed. Text Revision), by American Psychological Association, 2000a, Washington, DC: Author; and *The ICD-10 Classification of Mental and Behavioural Disorders: Clinical Descriptions and Diagnostic Guidelines*, by World Health Organization, 1992, Geneva: Author.

A less time-intensive diagnostic interview and one that may be more convenient to use in community clinical settings is the MINI International Neuropsychiatric Interview (Sheehan & Lecrubier, 1998), which diagnoses according to *DSM-IV* and *ICD-10* criteria. The MINI has 19 modules that evaluate 17 Axis I disorders. It has good validity and convergence with lengthier diagnostic interviews and takes approximately 15 minutes to administer. The SCID-IV, SADS, and MINI all require clinical

training to ensure appropriate administration and interpretation.

Psychometric Assessments for Unipolar and Bipolar Depression Episodes

The two gold-standard measures for depression used in clinical research are the Beck Depression Inventory-II

(BDI-II; Beck, Steer, & Brown, 1996) and the Hamilton Rating Scale for Depression (HAM-D; Hamilton, 1960). The BDI-II is a patient-rated instrument that contains 21 items covering somatic, cognitive, and emotional symptoms of depression over the preceding 2 weeks. The BDI-II is reliable, valid, and sensitive to treatment change (Beck et al., 1996). The total score ranges from 0 to 63, and it contains a cognitive/affective subscale and a somatic subscale. Administration time is 5–10 minutes. Clinical cutoffs place individuals in the normal (0–13), mild (14–19), moderate (20–29), or severe (30+) range of clinical severity.

The HAM-D is a clinician-administered instrument that has 17 items and a total score ranging from 0 to 52. There are four subscales of anxiety somatization, cognitive disturbance, psychomotor retardation, and sleep disturbance. Administration time is 15–20 minutes. A contemporary criticism of the HAM-D is that it contains outdated concepts, for it was based on a conceptualization of depression that is now decades old and that is only partly related to the contemporary operationalization as specified in the *DSM-IV* (Bagby, Ryder, Schuller, & Marshall, 2004). A revised version has been developed.

Psychometric Assessments for Bipolar Mania or Mixed Episodes

The Young Mania Rating Scale (YMRS; Young, Biggs, Ziegler, & Meyer, 1978) is the most widely used clinician-administered measure of mania severity and is intended for use among individuals with bipolar I or II disorder experiencing a manic, hypomanic, or mixed episode. It consists of 11 items assessing symptoms in the preceding 2 days and takes 10–30 minutes to administer. The YMRS has good interrater reliability and validity. The Bech-Rafaelson Mania Scale (Bech, Rafaelson, Kramp, & Bolwig, 1978) is a clinician-rated measure of mania severity. It contains 11 items that assess the presence of symptoms over the previous 3 days. The measure takes about 10 minutes to complete and has good interrater reliability, validity, and treatment sensitivity. Patients are classed in clinical severity categories according to total scores: mild (15–20), moderate (21–28), or severe (29–44). The Clinician-Administered Rating Scale for Mania (Altman, Hedeker, Janicak, Peterson, & Davis, 1994) is a 15-item severity measure. Factor analysis revealed that test items segregate into mania and psychosis; hence separate subscale scoring is used. The 10 mania items are derived from the SADS and *DSM-III-R* criteria. The test has good sensitivity, specificity, test-

retest reliability, and validity and is sensitive to treatment effects.

Self-rating scales for mania have received very little attention until recently because it was believed that characteristics of mania, such as uncooperativeness, agitation, distractibility, and poor judgment, rendered results unreliable. Recent empirical evidence has challenged this view (Altman, 1998). A well-validated self-report measure that is brief and easy to administer is the Altman Self-Rating Mania scale (Altman, Hedeker, Peterson, & Davis, 1997). It contains five items selected for their ability to differentiate manic from non-manic patients. It has very good test-retest reliability and is sensitive to treatment change. The Internal State Scale (Bauer et al., 1991) is a 17-item self-report measure that uses a visual analogue scale to rate items. It was developed to measure mixed symptoms in the preceding 24-hour period. Factor analysis identified four subscales of depression, well-being, activation, and perceptual conflict. Scoring is time consuming, and while some validation studies have been undertaken, psychometric information is preliminary. The Self-Report Manic Inventory (Shugar, Schertzer, Toner, & DiGasbarro, 1992) contains 48 items in a true-false response format and was originally developed as both a diagnostic and severity tool for mania. Statements apply to the preceding week when used to assess symptom severity. It has acceptable validity and test-retest reliability and is sensitive to change in manic symptoms with treatment.

ETIOLOGY OF UNIPOLAR MAJOR DEPRESSION

It is generally accepted that there is no precisely known etiology for depression. Modern consensus suggests that depression is a complex multifactorial condition with many biological and psychological pathways. A brief description of key models that map onto recognized theoretically based and empirically supported treatments will be given.

Biological Perspectives

Biological theories of depression propose that the cognitive, behavioral, and emotional expressions of depression are sustained by biological dysfunction. The existence of a genetic predisposition to depression is based on evidence from family, twin, and adoption studies. In a meta-analysis of five large and methodologically rigorous family studies of major depression, familiarity was

demonstrated by a relative risk of 2.8 for affected subject versus first-degree relative status (Sullivan, Neale & Kendler, 2000). Twin studies provide an index of heritability by comparing the rate of a feature in monozygotic (MZ) twins with those in dizygotic (DZ) twins. The higher the MZ-to-DZ ratio, the greater the degree of heritability is. The contribution of genetic influences to depression is estimated from twin studies to be between 31%–75% (McGuffin, Katz, Watkins, & Rutherford, 1996; Sullivan et al., 2000). Given that almost half of MZ twins do not develop depression, it is apparent that a significant amount of variance in liability to depression is environmental, that is, derives from psychosocial factors. Very few adoption studies have been reported. This methodology attempts to separate the effects of genetics from that of the environment by examining the incidence of depression in individuals living with the depressed biological parent and comparing it to the incidence of depression in offspring who live with an adoptive parent. Wender, Kety, Rosenthal, Schulsinger, Ortmann, and Lunde (1986) reported an eight-fold increase in unipolar depression among the biological relatives of these indexed cases. Research in genetic epidemiology and behavioral genetics has suggested a genetic contribution, but the mode of inheritance is unclear.

The monoamine deficiency hypothesis posits that an increase in synaptic neurotransmitters of noradrenaline and serotonin lead to improvements in mood (Delgado, 2000). This theory has been supported by our understanding of the pharmacology of antidepressant medication, which blocks the reuptake of these neurotransmitters or inhibits the enzyme monoamine oxidase, which normally acts to catabolize the neurotransmitters (Mann, 2005). This theory has been useful in predicting antidepressant activity of new pharmaceutical compounds, yet the significant response of trial participants to placebo compounds may be considered a weakness (Belmaker & Agam, 2008).

The hypothalamic-pituitary-adrenal (HPA) axis theory describes depression as a result of overactivity in the HPA axis in response to stress (Gillespie & Nemeroff, 2005). This activity is determined by the release of corticotrophin-releasing hormone from the hypothalamus, which activates the release of adrenocorticotrophic hormone from the pituitary. This hormone stimulates the secretion of cortisol from the adrenal glands. Cortisol binds to receptors in the brain, inhibiting further release of corticotrophin-releasing hormone from the hypothalamus and adrenocorticotrophic hormone from the pituitary. Overactivity of the HPA axis in depression had been attributed to the reduced function of the corticosteroid receptors, resulting in the inability of cortisol

to inhibit HPA axis activity (Holsboer, 2000). Two hypotheses have been advanced to explain the association between high HPA axis activity and depression. The first suggests that depressive symptoms are a consequence of a high level of circulating cortisol in the brain. An alternate hypothesis is that depressed individuals may be resistant to the effects of cortisol, and HPA axis increases activity to compensate for this (Nemeroff, 1996; Pariante & Miller, 2001).

Psychosocial Perspectives

The most empirically supported psychological theory of depression is Beck's cognitive theory (1967, 1976, 1983). Cognitive theory is based on the premise that everyday events are ambiguous and can be interpreted in a negative, benign, or positive way. That is, humans respond primarily to cognitive representations of their environment, rather than to the environment per se. Extrapolated to depression, negatively biased idiosyncratic meanings and interpretations are key to the experience of depression.

According to cognitive theory, our cognitive schemata (characteristic way of viewing the self, others, and the world) arise from the interaction of distal factors such as early experiences and temperament. For some individuals, these interactions may result in the development of enduring, dormant depressive schemata. Schemata comprise core beliefs ("I am a failure," "I am worthless," "I am unlovable," "No one really cares about me," "People are untrustworthy"), assumptions ("If I fail at my job then I am a failure," "If I express my needs, then I will be rejected"), and negative automatic thoughts ("There's no point in trying to talk to my boss about the problem because he won't listen," "I didn't have enough time to finish the last question on the test so I guess I have failed," "I've spilt something on my shirt, now everyone in the office will think I'm an idiot"). A depressive schemata may lie dormant but be activated by proximal critical incidents, such as adverse life events, that arouse a causal sequence involving the individual's negative automatic thoughts and associated biased cognitive processes. The depressive schemata negatively influence the way in which depressed individuals think about themselves, the world in which they live, and the future. Beck called this the "cognitive triad" of negative automatic thinking, with core features of hopelessness, worthlessness, and negative expectations. Ultimately, Beck viewed cognition as both a cardinal symptom of depression and a unique factor that contributes to the onset, maintenance, and worsening of depression. Cognitive theory proposes that to alleviate

depression symptoms, one needs to replace maladaptive schemata with adaptive schemata. Strengths of cognitive theory are that it takes developmental experiences into account, it has testable hypotheses that have been investigated, and it has been explored and refined by research in basic cognitive science (for an extensive review, see Harvey, Watkins, Mansell, & Shafran, 2004; Matthews & MacLeod, 2005).

The behavioral model has also made a unique contribution to our understanding of the etiology and maintenance of depression. Learning theory explains depression in terms of an operant repertoire shaped by the interaction of the individual with his or her environment. All behaviors, including depressed behaviors, are a two-way process: response-contingent environmental reinforcement shapes the individual's behavior, and the individual's behavior in turn affects the environment. As a result of these dynamic processes, the person with depression withdraws from social contact, increases avoidance, and develops a depleted adaptive repertoire of behaviors (Costello, 1972; Ferster, 1973; Lewinsohn, Youngren, & Grosscup, 1979).

The role of interpersonal difficulties in the etiology and development of depression is well established (Frank & Spanier, 1995; Klerman, Weissman, Rounsaville, & Chevron, 1984). Interpersonal psychotherapy for depression, a highly regarded treatment, was pioneered by Klerman and colleagues (1984) and draws from the interpersonal and psychobiological theories of Sullivan (1953), Meyer (1957), and Bowlby (1980). Meyer developed a psychobiological theory of mental illness and argued that early psychosocial experiences are pivotal to emotional well-being and mental illness. Sullivan, a student of Meyer's, continued this work and played a significant role in the articulation of the interpersonal theory and in advancing interpersonal relations as an etiopathogenesis of depression. Bowlby proposed attachment theory, the idea that human beings have an innate, fundamental drive to seek closeness with others, and that disruption to this process (e.g., separation, death, loss of a relationship) can lead to mental illness. Klerman and colleagues integrated these findings into their interpersonal psychotherapy and theory of depression. They suggest that disruptions to personal relationships, complicated bereavement and/or unresolved grief, role transitions, and interpersonal deficits (social skills) precipitate onset and/or maintain depression symptoms.

Integrating the Theory

Diathesis-stress models propose that a stressor (most typically a negative life event) interacts with a latent

diathesis or vulnerability—for example, a genetic predisposition, biological traits, or psychological factors, or their combination—to produce the depressive syndrome. Research has found that negative life events are proximal to the beginning of an episode of depression (see Brown & Harris 1978). Typically these events can be characterized as “exits” (real or symbolic), examples being interpersonal loss, severe disruption to one's social supports, physical illness, loss of self-esteem, or humiliation. While latent diatheses are necessary to cause depression, they are generally not sufficient in isolation. Although a negative life event typically precedes depression, many people faced with similar stressors do not become depressed, lending validity to the diathesis-stress formulation.

BIPOLAR DISORDER

Biological Perspectives

Bipolar disorder has a very strong biological diathesis in comparison to many other psychiatric disorders. Family, twin, and adoption studies indicate that bipolar disorder is 10 times more common in a person who has a first-degree relative with bipolar disorder than in the general population. Therefore, instead of the approximate 1% risk for members of the general population, the average risk for someone with a first-degree relative with bipolar disorder rises to just over 10%. The genetic heritability of bipolar disorder is therefore greater than that of unipolar depression and similar to that of schizophrenia (Goodwin & Jamison, 2007). There is no indication of a single pathogenic gene; rather the true picture is likely to represent a complex array of multiple genes, each making a small contribution. Genetic linkage and association studies are underway to shed light on the genetics of bipolar disorder. To date, promising findings have occurred in genes influencing the circadian rhythm, affect-related brain neurotransmission, and mitochondrial disease. Yet it will be some time before a clear understanding of genetic causes is determined, for even if a particular gene is identified via these studies, we do not know whether the association is causal or not. For recent reviews of the current status of genetic research, the interested reader is referred to Farmer, Elkin, and McGuffin (2007) and Kato (2007).

Given the success of medications in the treatment of bipolar disorder, there has been an understandable research focus on the neurochemistry that may cause or perpetuate bipolar disorder. This task has been made

particularly difficult by the nature of the syndrome to be explained, with its manifestation of depressed, manic, and mixed episodes. It is also heterogeneous and episodic in presentation and a range of medication classes have been found to produce a response. The clinical picture of bipolar disorder is characterized by disturbances in mood, appetite, arousal, sleep, circadian rhythms, and endocrine functioning. Not surprisingly, disturbances in governing systems such as the dopaminergic, serotonergic, monoamine, acetylcholine, GABAergic, noradrenergic, and cholinergic systems and the HPA axis have been observed.

Chronobiological disruption could be a factor in the production of bipolar symptoms. Circadian rhythm disruptions of various kinds have been found to relate to mood symptoms and sleep patterns (Goodwin, Wirz-Justice, & Wehr, 1982; Teicher, Glod, Magnus, Harper, Benson, Krueger, & McGreenery, 1997). For example, episodes of mania have been found to be related to sleep disturbance or circadian rhythm disruption. Many people also experience seasonal patterns in mood.

Research over the last 10 years has noted neuroanatomical changes in people with bipolar disorder. Specifically, enlarged third ventricles/lateral ventricles (Bearden, Hoffman, & Cannon, 2001) and subcortical and periventricular white matter hyperintensities (Woods, Brennan, Yurgelan-Todd, Young, & Panzarino, 1995). In terms of brain functioning, there is evidence of reduced metabolic activity in the frontal lobes of people with bipolar disorder (Gyulai, Alavi, Broich, Reilley, Ball, & Whybrow, 1997).

Psychosocial Perspectives

Johnson, Cueller, Ruggero, White, Winett-Perlman, Goodnick, and Miller (2008) have conducted extensive research into the role of stressful life events in precipitating episodes of bipolar disorder. Negative life events appear to be associated with the onset of episodes of bipolar depression, although the contribution is smaller and less predictable than in depression. This is presumably due to the high biological loading of bipolar disorder (Johnson et al., 2008). Negative life events do not appear to have a relationship with onset of mania.

As is the case with unipolar depression, negative life events are more associated with initial episode onset rather than episode recurrences, with a reduced threshold for stress occurring after the initial episode (Hlastala, Frank, Kowalski, Sherrill, Tu, Anderson, & Kupfer, 2000). It may be that cognitive, personality, or behavioral diatheses operate in a more residualized manner following remission and recovery, rather than the dor-

mant state preceding first episode onset. Alternatively, Post (1992) at the National Institute of Mental Health has proposed the neurophysiological model of kindling-behavioral sensitization. The model was derived from animal research that discerned the respective processes of electrophysiological kindling (the progressive reduction of seizure thresholds) and behavioral sensitization (progressive enhancement of behaviors in response to psychomotor stimulants). Direct transpositions of animal models to humans are necessarily problematic, yet the kindling-behavioral sensitization model is stimulating interest as a conceptual heuristic.

There is evidence that interruptions to the circadian rhythm (e.g., through variation in the structure of one's sleeping, feeding, physical activity, or social routines) and intense goal pursuit or goal attainment can trigger mania (Johnson et al., 2008; Malkoff-Schwartz et al., 2000). Psychodynamic theorists have advanced the manic defense hypothesis, whereby it is hypothesized that individuals with bipolar disorder experience greater emotional reactions to failures. Coupled with low self-esteem, this may precipitate the intense pursuit of goal accomplishment and grandiose ambitions and lead to a cognitive defensiveness style characterized by inflated self-esteem. Empirical tests of this model are numbered (Lyon, Startup, & Bentall, 1999).

There is weak evidence (due to primarily correlational designs) for the role of high expressed emotion in families. High expressed emotion refers to a critical, hostile, and/or emotionally overinvolved interactional style. A high expressed emotion environment is related to increased severity of illness and risk of relapse (Miklowitz, Goldstein, Neuchterlein, Snyder, & Mintz, 1988; Miklowitz, Wisniewski, Miyahara, Otto, & Sachs, 2005).

Early views of depression understood disordered cognitions as a symptom of the illness. However, Beck's conceptual model, which has been so important to our understanding of depression, suggests that cognition may be more than merely a symptom of bipolar disorder. Research is underway to pinpoint the unhelpful cognitive appraisal styles and specific beliefs that may affect the severity and course of illness (Mansell & Pedley, 2008). One potentially interesting line of research has been followed by Lam and colleagues. They found that goal attainment beliefs were more strongly endorsed by people with bipolar disorder than unipolar depression (Lam, Wright, & Smith, 2004). For example, goal attainment beliefs include "A person should be able to do well at everything." A pessimistic attributional style may also be implicated (Reilly-Harrington, Alloy, Fresco, & Whitehouse, 1999).

12.2

Depression Pharmacotherapies

ANTIDEPRESSANT CLASS	EXAMPLES
Monoamine oxidase inhibitor (MAOI)	Phenelzine, tranylcypromine, iproclozide
Tricyclic antidepressant (TCA)	Clomipramine, nortriptyline, desipramine
Tetracyclic antidepressant (TeCA)	Maprotiline, mirtazapine
Selective serotonin reuptake inhibitor (SSRI)	Fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram
Serotonin and noradrenaline reuptake inhibitor (SNRI)	Venlafaxine, sibutramine, milnacipran, duloxetine
Norepinephrine-dopamine reuptake inhibitor (NDRI)	Bupropion
Serotonin-2 antagonist/reuptake inhibitor (SARI)	Nefazodone, trazodone
Selective serotonin reuptake enhanced (SSRE)	Tianeptine
Noradrenergic and specific serotonergic antidepressant (NaSSA)	Mirtazapine, mianserin
Serotonin noradrenaline dopamine reuptake inhibitor (SNDRI)	Nomifensine, brasofensine, tesofensine
Reversible inhibitors of monoamine oxidase A (RIMA)	Moclobemide
Noradrenaline reuptake inhibitor (NRI)	Reboxetine

EVIDENCE-BASED MANAGEMENT OF UNIPOLAR MAJOR DEPRESSION

Pharmacotherapy

Since the first tricyclic antidepressant and the monoamine oxidase inhibitors (MAOIs) were introduced in the 1950s, pharmacotherapy for depression has become a well-established treatment. Pharmacotherapies act on the serotonin, dopamine, and other affect-related brain neurotransmitter systems. Hundreds of controlled trials have examined the efficacy of pharmacotherapy for unipolar, nonpsychotic depression. Availability of pharmacotherapies varies across countries and many newer antidepressant agents are undergoing evaluation of efficacy, tolerability, and safety. Classes and examples of antidepressants that have been developed are shown in Table 12.2.

The empirical review presented in the National Institute for Clinical Excellence (NICE; 2004) clinical practice guidelines for depression show supporting evidence for tricyclic antidepressants, SSRIs, moclobemide, MAOIs, noradrenergic and specific serotonergic antidepressants, serotonin and noradrenaline reuptake inhibitors, reboxetine, and the herbal remedy St. John's wort. The highest quality of evidence is demonstrated for the SSRIs, reboxetine, and phenelzine. The American Psychiatric Association (2002b) guidelines suggest that the SSRIs, desipramine, nortriptyline, bupropion, and venlafaxine are optimal candidates for most patients.

Limitations arising from pharmacotherapy include the occurrence of side effects, the high rate of relapse following discontinuation (Evans, Hollon, DeRubeis, Piasecki, Grove, Garvey, & Tuason, 1992), and non-adherence to the continuation phase of treatment.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is widely regarded as a first-line treatment for nonpsychotic, unipolar depression in practice guidelines (American Psychiatric Association, 2000b; National Institute for Clinical Excellence, 2004). CBT is a structured treatment based on Beck's (1967, 1976) widely accepted cognitive theory of emotional disorders. The treatment aims to alter unhelpful cognitions and behaviors that maintain depression symptoms. Standard CBT is administered once weekly for 1 hour over 12–20 weeks. Typical components include behavioral activation (e.g., pleasant events scheduling, graded task assignments, activities of mastery), cognitive restructuring, behavioral experiments to test automatic thoughts, relaxation and stress management, and problem-solving and active coping skills training.

Of all the psychotherapies for depression, CBT has been the most investigated and has the strongest empirical basis. An influential landmark efficacy study was the multisite National Institute of Mental Health Treatment of Depression Collaborative Research Program (Elkin et al., 1989), which compared 250 patients randomly assigned to a 16-week program of CBT, interpersonal psychotherapy (IPT), imipramine plus clinical management, or pill placebo with clinical management. All three treatments were effective in treating depression; imipramine was found to be most effective, followed by CBT and IPT, and placebo. Remission was achieved in 65% of CBT completers and 49% of the intent-to-treat CBT patients.

Between 1977 and 1996 there were 78 controlled CBT clinical trials conducted among some 2,765 patients (Gloaguen, Cottraux, Cucherat, & Blackburn, 1998). The sheer volume of controlled and active comparator trials does not lend itself easily to brief empirical review. The majority of findings have supported the efficacy of CBT for unipolar depression. Meta-analyses have rendered additional important findings in support of CBT; CBT should be the first-line treatment for depression (National Institute for Clinical Excellence, 2004), CBT is superior to waiting-list control and attention control (Gaffan, Tsaousis, & Kemp-Wheeler, 1995), CBT is superior to antidepressants in reducing depressive symptoms (Gloaguen et al., 1998), the average client treated with CBT has a better outcome than 98% of control subjects (Dobson, 1989), patients treated with CBT are half as likely to relapse as patients treated with antidepressants (29% vs. 59%; Gloaguen et al., 1998), and CBT has a rapid treatment effect, with the degree of change not strongly related to length of treatment (Dob-

son, 1989). In addition, "effectiveness" studies have supported the real-world effectiveness and transportability of individual and group-format CBT for unipolar depression (Merrill, Tolbert, & Wade, 2007; McEvoy & Nathan, 2007).

Interpersonal Psychotherapy

IPT is a time-limited, structured, weekly treatment (12–16 weeks) for nonpsychotic unipolar depression and is recommended in the American Psychiatric Association (2000b) and National Institute for Clinical Excellence (2004) guidelines. IPT is based on the premise that interpersonal factors play a key role in the onset and maintenance of depression. IPT was pioneered by Klerman and colleagues (1984). The patient's illness is formulated in interpersonal dimensions and treatment is centered on resolving issues in one or more key domains: (1) interpersonal disputes, (2) role transitions, (3) grief, and (4) interpersonal deficits.

RCTs have been used to evaluate IPT. The first, conducted by the originators of IPT, involved the random allocation of 81 patients with depression to treatment with IPT, amitriptyline, and combined IPT and amitriptyline, and a low-contact control condition (DiMascio, Weissman, Prusoff, Neu, Zwillig, & Klerman, 1979). All three treatments were superior to control, and the monotherapies were equivalent. Amitriptyline produced changes in primarily somatic and vegetative depressive symptoms, while IPT affected primarily cognitive and affective symptoms. IPT benefits were sustained at 1-year follow-up (Weissman, Klerman, Prusoff, Sholomskas, & Padian, 1981). The National Institute of Mental Health Treatment of Depression Collaborative Research Program mentioned earlier was the second RCT to be conducted (Elkin et al., 1989). Sixty-one patients with depression were randomized to IPT. Remission (depression severity in the normative range) was achieved in 70% of completers and 56% of the intent-to-treat sample and was higher than in any other arm of the study. IPT also had the lowest dropout/withdrawal rate of 23% (vs. 35%–45% for the other modalities). Luty and colleagues (2007) randomized 177 patients to IPT or CBT. Patients in both treatments improved significantly, and there was no difference in depression severity or percent improvement at the end of treatment. Response was defined as a 60% or greater improvement in symptoms. Forty-five percent of the IPT sample were "responders," compared to 59% of the CBT sample. IPT has been compared to pharmacotherapy and has produced good outcomes (e.g., Brown, Schulberg, Madonia, Shear, & Houck, 1996; Elkin et al., 1989; Sloane,

Stapes, & Schneider, 1985; Weissman et al., 1979). There is some evidence that IPT combined with pharmacotherapy may produce a better outcome than IPT alone (National Institute for Clinical Excellence, 2004).

Monotherapy or Combination Treatment

The American Psychiatric Association (2000b) guidelines recommend monotherapy with an antidepressant or specific, effective psychotherapy for mild to moderate depression. They recommend antidepressant monotherapy or combination therapy (antidepressant + a specific psychological intervention) for severe depression. The NICE (2004) guidelines suggest using a specific, effective psychotherapy for mild and moderate depression and combination treatment (antidepressant + CBT) for severe depression. The more severe the depressive disorder becomes, the more consideration should be given to a broad-spectrum approach targeting cognitive-behavioral, interpersonal, and biological mechanisms.

BIPOLAR DISORDER

Pharmacotherapy

Pharmacotherapy is the first-line treatment for bipolar disorder and is targeted to the acute (mania, mixed, or depressive episodes) and maintenance phases of the illness. Treatment of bipolar disorder was revolutionized by the introduction of lithium carbonate by John Cade in 1949, in one of the first successful uses of a drug to treat mental illness. There is now a range of drugs that are used to treat bipolar disorder—including anticonvulsants (e.g., valproate, lamotrigine, carbamazepine), antipsychotics (e.g., olanzapine, haloperidol), antidepressants, and combination treatments. The area of medication treatment for bipolar disorder is evolving rapidly, with treatment guidelines requiring regular updates as new treatments emerge and are trialed. For this reason all clinicians working in this field need to maintain current knowledge of evidence-supported medication treatments.

Acute Mania and Mixed Episodes

Lithium is a first-line treatment for mania and is the most empirically validated pharmacotherapy for mania and mixed episodes. Two-thirds of patients with acute

mania show a remission of manic symptoms with lithium treatment (Goldberg, 2000) and controlled trials have shown superiority to placebo for mania and mixed episodes. Double-blind, placebo-controlled trials have demonstrated that lithium prevents episode recurrence, though this effect diminishes over time in 20%–40% of patients (Dubovsky, Davies, & Dubovsky, 2004). An advantage of lithium is that it appears to have a significant preventive effect against suicide and self-harm behavior (Cipriani, Pretty, Hawton, & Geddes, 2005). A negative aspect is the risk of toxicity and the consequent requirement for careful monitoring of blood levels. There is also a high likelihood of relapse following discontinuation or noncompliance; for example, more than half of patients relapse following lithium discontinuation, and usually within 1 year (Baldessarini, Suppes, & Tondo, 1996).

The anticonvulsant valproate (also known as divalproex) is another first-line treatment for mania and mixed episodes. The efficacy of valproate is superior to that of placebo in treating bipolar mania in randomized, placebo-controlled trials (Bowden et al., 1994; Brennan, Sandyk, & Borsook, 1984; Emrich, von Zerssen, Kissling, & Moller, 1981; Pope, McElroy, Keck, & Hudson, 1991). The treatment response rate ranges from 48% to 53% (American Psychiatric Association, 2002). There is limited research on efficacy for acute mixed episodes. The antipsychotic olanzapine is now also considered a first-line treatment for mania (National Institute for Health and Clinical Excellence, 2006). The anticonvulsant carbamazepine has shown comparative efficacy to lithium (Lerer, Moore, Meyendorff, Cho, & Gershon, 1987; Small, Klapper, Milstein, Kellams, Miller, Marhenke, & Small, 1991) and has been evaluated in at least 19 controlled trials.

Acute Bipolar Depression

Standard antidepressants combined with an anti-manic agent have been recommended as the first-line treatment for bipolar depression, particularly for more severely ill patients (Goodwin, 2003). Standard antidepressant monotherapy is not recommended. Although antidepressant monotherapy appears comparatively effective for bipolar and unipolar depression episodes, monotherapy can induce mania and rapid cycling in bipolar patients (Bottlender, Rudolf, Strauss, & Möller, 2001). When antidepressant monotherapy is combined with lithium, valproate, or antipsychotics, “switching” seems less likely to occur. The anticonvulsant lamotrigine appears effective as an acute and maintenance treat-

ment for bipolar depression in the very small number of studies that have been conducted.

Maintenance Treatment

The natural course of the illness is characterized by a high rate of episode recurrence; therefore relapse is common following all acute, time-limited pharmacotherapies. Emphasis in treatment has therefore been placed on long-term “maintenance treatments.” Lithium, valproate, and olanzapine are recommended as first-line maintenance treatments (American Psychiatric Association, 2002b; National Institute for Health and Clinical Excellence, 2006). Lithium is considered the treatment of choice due to its prophylactic effects on both manic and depressive episodes (American Psychiatric Association, 2002b; Goodwin, 2003). Possible alternatives to consider include lamotrigine, carbamazepine, and oxcarbazepine (American Psychiatric Association, 2002b).

Adjunct Psychosocial Interventions

Pharmacotherapy is undoubtedly the most effective long-term treatment for bipolar disorder, yet it has been increasingly recognized that bipolar interventions require a psychosocial adjunct to address the psychosocial corollaries of illness and the complex array of psychosocial factors that may precipitate episode recurrence. For example, medication non-adherence is a significant barrier to wellness in this population and is believed to occur in over 60% of patients. Non-adherence to medication reduces the time between bipolar episodes and causes more frequent hospitalizations. Irregularity in routines and harmful family emotional environments are related to relapse.

It is becoming clear that psychosocial interventions can reduce relapse rates. A recent meta-analysis of RCTs showed that psychosocial interventions reduce relapse rates a further 40% beyond treatment as usual (Scott, Colom, & Vieta, 2007). Psychosocial therapeutic models that have been investigated include CBT, psychoeducation (individual, group, and family), interpersonal and social rhythm therapy (IPSRT), and family-focused treatment (FFT). There are certain core characteristics that are common to all psychosocial treatments in bipolar disorder—education, a focus on early warning signs and triggers for episodes, and development of detailed and individual action plans. These features have been referred to as the “core psychosocial agenda” (Bauer & McBride, 2003). Aside from these core features, each of

the specific treatment models focuses on targeting different hypothesized etiological factors.

Psychoeducation

Psychoeducation is an important component of adjunct psychosocial treatment for bipolar disorder, as evidenced by its inclusion in all psychosocial intervention protocols. Education about bipolar disorders (symptoms, chronicity, prodromal signs, relapse precipitants, treatments), pharmacotherapy adherence, the stress-diathesis model, lifestyle regularity, emergency action plans, and community resources are essential aspects of patient care and management. Psychoeducational programs can be offered individually, or with family or spousal involvement.

To date, controlled trials of adjunct psychoeducation programs among bipolar patients have shown improvements in general psychopathology (Clarkin et al., 1990; Clarkin, Carpenter, Hull, Wilner, & Glick, 1998), improvements in knowledge of bipolar disorder (van Gent & Zwart, 1991), family change from high to low expressed emotion (Honig, Hofman, Rozendaal, & Dingemans, 1997), superior medication adherence (Clarkin et al., 1998), fewer relapses and reduced risk of mania (Perry, Tarrier, Morriss, McCarthy, & Limb, 1999; Simon, Ludman, Bauer, Unützer, & Operskalski, 2006; Simon, Ludman, Unützer, Bauer, Operskalski, & Rutter, 2005), and better employment outcomes (Perry et al., 1999). Inconsistent outcomes have been reported for hospitalization rate and medication compliance (Clarkin et al., 1998; Colom et al., 2003; Perry et al., 1999; Simon et al., 2005, 2006; van Gent & Zwart, 1991). No beneficial effect on number of psychiatric emergency room visits was detected (Simon et al., 2005, 2006). Psychoeducational programs do not appear to affect the number of bipolar depression relapses or time to relapse (Perry et al., 1999; Simon et al., 2005, 2006). Miller, Keitner, Ryan, Uebelacker, Johnson, and Solomon (2008) found that an adjunct family psychoeducation group significantly improved course of illness in individuals with acute bipolar disorder, yet the effect was limited to high-impairment families. Those from high-impairment families showed a significantly lower frequency of and time spent in a depressive episode than those treated with medication only.

Cognitive-Behavioral Treatment

All CBT programs are based on Beck's model but adapted to formulations specific to bipolar disorder. Protocols

typically involve psychoeducation about the illness and the diathesis-stress model, skills to monitor and manage mood and prodromes, problem-solving and coping skills, cognitive therapy to challenge dysfunctional thinking styles, sleep stabilization and promotion of a regular routine, relapse prevention, and CBT skills for depression and comorbid disorders. CBT has been supported as an adjunct treatment in RCTs and is typically associated with a lower relapse rate and fewer hospitalizations than conventional treatment (Ball, Mitchell, Corry, Skillecorn, Smith, & Malhi, 2006; Cochran, 1984; Lam et al., 2003; Miklowitz et al., 2007; Schmitz, Averill, Sayre, McCleary, Moeller, & Swann, 2002; Scott, Garland, & Moorhead, 2001). A recent large-scale pragmatic trial indicated that CBT may only benefit those who have experienced 12 or fewer bipolar episodes (Scott et al., 2001).

Interpersonal and Social Rhythm Therapy

IPSRT is based on the premise that normal disruptions to the circadian rhythm occurring due to stressful life events and irregularity in routines (sleeping, eating, social) may lead to bipolar episodes in individuals with bipolar disorder. IPSRT aims to prevent recurrences of bipolar disorder episodes, to increase stability of mood between episodes, and to reduce suicidal behavior and has been manualized (Frank, 2005). IPSRT seeks to facilitate medication adherence, promote recognition and adoption of strategies that maintain euthymic mood, stabilize routines, improve interpersonal relationships, and reduce interpersonal distress. Key treatment strategies include communication analysis, role-plays, and decision analysis. Two large RCTs have examined IPSRT. Frank and colleagues (1997) evaluated IPSRT in an acute- and maintenance-phase format among individuals with bipolar I disorder. Individuals with acute bipolar disorder were randomly assigned to one of four groups: acute IPSRT/maintenance IPSRT, acute IPSRT/maintenance control (intensive clinical management), acute control/maintenance IPSRT, and acute control/maintenance control. The acute treatment involved weekly sessions of IPSRT until the subject achieved a predefined standardized mood symptom rating, then maintenance commenced. Maintenance treatment involved 12 weekly sessions of IPSRT and 2 monthly sessions thereafter (for 2 years). At 2 years, individuals who received acute IPSRT had a longer duration to episode recurrence irrespective of the type of maintenance received and showed greater stabilization of social rhythms. A comparison of maintenance IPSRT and maintenance control showed no significant differences

in time to episode recurrence. The Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) was a large multicenter comparative trial of three adjunct psychosocial interventions for bipolar I and II depressive episodes (Miklowitz et al., 2007). Sixty-five percent of IPSRT patients recovered within 1 year and the median time to recovery was 127 days.

Family Therapy

Family therapy for bipolar disorder is based on the assumption that family factors play a role in the course and severity of the illness. Episodic recurrences have been linked empirically to family environments characterized by high expressed emotion and negative communication patterns. Family therapy aims to provide education about the illness, formulate adaptive illness responses, promote healthy communication, reduce expressed emotion, reduce family stress, assist in the reestablishment of adaptive relationships after an episode, and educate families on crisis management. Psychoeducation, communication training, and problem solving are key components of treatment. A structured, manualized program called family-focused treatment has undergone the most testing (Miklowitz, 2008).

Controlled trials have shown that adjunct FFT for bipolar patients leads to greater improvement in family functioning and mood symptoms, fewer relapses, and a longer survival time to relapse 1 to 2 years after treatment in comparison to adjunct crisis management (Miklowitz, George, Richards, Simoneau, & Sudath, 2003; Simoneau, Miklowitz, Richards, Saleem, & George, 1999). In a comparative 2-year trial of FFT and psychoeducation, the treatments led to equivalent rates of relapse over the 1-year active treatment period (approximately 50%), yet when multiple relapses were modeled, results favored FFT. At the end of the second year, a lower hospitalization rate was observed for FFT-treated individuals (12% vs. 60%) (Rea et al., 2003). In the STEP-BD trial of patients with acute bipolar depression, the recovery rate was 77% for FFT with a median time to recovery of 103 days. Miller and colleagues (2008) randomly assigned bipolar I patients to pharmacotherapy, family therapy and pharmacotherapy, or family psychoeducation and pharmacotherapy. There were no differences between intervention groups during the 28-month course of the study on any outcomes. Outcomes measured were number of depressive, manic, and mixed episodes; percent of time in an episode or symptom-free; percent recovered; and percent relapsed. Post hoc analysis showed that the addition of either of the family interventions significantly reduced depres-

sion episodes and the proportion of time spent in a depressive episode among high-impairment families but had no effect on low-impairment families.

CLINICAL APPLICATIONS OF EVIDENCE-BASED MANAGEMENT

Evidence-based management fundamentally relies on well-specified theoretical models. We have outlined a contemporary understanding of the development and remediation of depression and bipolar disorder pathology. Our site, the Centre for Clinical Interventions, operates treatment programs for individuals that meet clinical criteria for specific psychological conditions, and we have sought to transport empirically derived treatment to our clinical setting.¹ In this next part of the chapter, we turn to a case-guided approach to describe empirically based treatment programs for depression and bipolar disorder implemented at our site. It is important to note that our formulations and treatment programs are CBT focused, though other valid treatment approaches exist and were described earlier.

Unipolar Major Depression

Susan is a 35-year-old woman working part-time as a lawyer. She has been married for 8 years and has a 2-year-old daughter. Susan's mother died of a sudden heart attack 18 months earlier and Susan reports experiencing low mood, impaired concentration, low energy, and anhedonia since then, and difficulty "getting over" the loss of her mother. Susan has one or two close friends and a wider circle of acquaintances, but she does not see them often for fear of boring them with her depression. She has largely withdrawn from activities she previously enjoyed, such as tennis and meeting up with other mothers from her children's child care center. She describes her husband as generally supportive but states that she tries to hide the depth of her depression from him, because he may be critical of her. She

reports feeling guilty, because she perceives she is failing at work and as a mother and wife. She denies any unusual mood elevations or symptoms of hypomania or mania. She reports a family history of depression on her father's side. Susan wants help for her difficulties and has sought referral to a psychologist.

Diagnosis and Symptoms

Susan was interviewed by a clinical psychologist who administered the MINI diagnostic interview. She was assigned the diagnosis of major depressive disorder (single episode, moderate). Symptoms consistent with major depression included low mood and energy, anhedonia, difficulty concentrating, insomnia, and guilt. Susan has been experiencing these symptoms most of the day, on most days, for longer than 2 weeks. Susan obtained a score of 28 on the BDI-II, placing her in the moderate severity range.

Case Formulation

Susan's case formulation is depicted in Figure 12.1. A significant predisposing factor is Susan's family history of depression. The main precipitating factor for her current depressive symptoms appears to be her mother's death 18 months ago. She had her second child 6 months prior to her mother's passing, which represents a significant role transition in her life.

A number of factors appear to be perpetuating Susan's symptoms. Cognitively, she holds problematic beliefs and assumptions about herself, others, and possibly the grieving process. She appears to hold negative core beliefs about herself as weak, a failure, and unlovable. She appears to have somewhat unrealistic expectations about the grieving process. She seems to believe that her difficulty "getting over" the loss of her mother is further evidence of her weakness, which, along with her belief that others are likely to be critical and rejecting, leads her to hide her symptoms from her husband and friends. Her reluctance to recruit social support also means that other people are unable to fulfill some of the roles her mother played in her life. Her emotional avoidance may be perpetuating her depression by inhibiting her ability to process the meaning of her loss.

A number of behavioral factors appear to be perpetuating Susan's symptoms. For instance, her withdrawal from tennis and social encounters that she previously enjoyed has reduced her opportunity to experience pleasure in her life. She now spends more time alone ruminating about her depression, which in turn exacerbates her low mood. Susan's reluctance to rely on her

1. The Centre for Clinical Interventions (CCI) is a specialist statewide program that is administered through the public health service in Western Australia. CCI offers a clinical outpatient service for adults suffering from mood, anxiety, and eating disorders. The center is staffed by clinical psychologists and a research psychologist. The clinical service provided by CCI is based on current evidence-supported practice and aims to meet the needs of clients. As CCI forms part of the public mental health system, the service offered is free. The center also conducts clinically applied psychosocial research, and staff provide training and supervision for various psychological interventions.

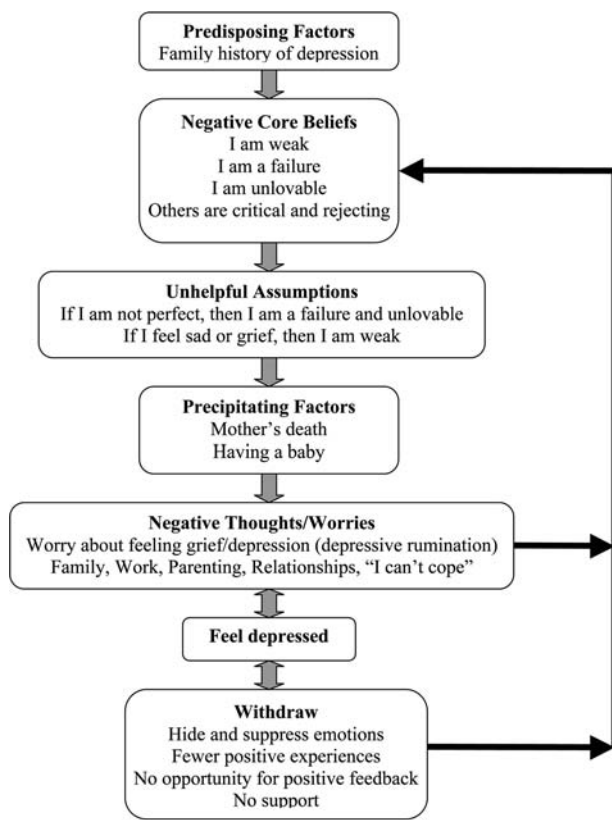

Figure 12.1 Susan's clinical case formulation.

social supports and emotional avoidance prevents her from directly challenging unhelpful assumptions that others will reject her, and that she is weak, a failure, and unlovable.

Treatment Plan

A program of CBT is recommended by clinical guidelines for moderate depression, and it appears that it would be helpful for Susan. In our clinic we would offer Susan standard individual CBT (Nathan, Rees, Smith, & O'Donnell, 2001) based on Beck's (1979) treatment model. Treatment comprises weekly 1-hour sessions, with 12 to 20 sessions comprising a reasonable trial. The program we offer proceeds through three main treatment phases. The program is manualized and provides detailed instructions for the administration of each practice element.² The program has been benchmarked against RCTs (McEvoy & Nathan, 2007).

2. Details about the treatment program as well as patient handouts and worksheets are available online at <http://www.cci.health.wa.gov.au>

Phase 1: Treatment Orientation, Goal-Setting, and Psychoeducation. Initial therapy sessions span goal setting, socialization to the treatment model, formulation, developing hope for change, and baseline measurement (if this was not done during assessment). Goals for Susan in this phase would include (1) improving her mood, (2) increasing activity levels (pleasure, mastery), (3) increasing her use of support networks, (4) and reducing rumination and worry. Early improvements in mood not only improve the client's quality of life but also imbue the therapy and therapist with credibility and offer hope that further change is possible. A priority is socializing the client to the model by collaboratively developing a cognitive-behavioral formulation (see Figure 12.1 for an example formulation).

Once the client understands the feedback loops that maintain the disorder, the rationale for the techniques applied in therapy should be clear. Therapists usually spend some time at this point providing clients with a summary of techniques that may be applied in therapy to demonstrate how the feedback loops can be eroded. This process is designed to offer hope for change and to motivate the client to engage in therapy. For Susan's case, the therapist might describe cognitive restructuring targeting her negative automatic thoughts, unhelpful assumptions, and core beliefs. The basic principles behind behavioral experiments might also be described, as these would also be helpful for challenging her beliefs. Her withdrawal might be targeted with a combination of activity scheduling (pleasure and achievement) and graded support seeking.

Baseline measures should be administered so that change across treatment can be assessed (e.g., the BDI-II or HAM-D). Behavioral indices might include the number of times she meets with her friends, engagement in other pleasant or achievement-based activities, time spent with family members, and number of missed work deadlines over a 1- or 2-week baseline period. These measures are readministered and reviewed intermittently throughout therapy.

Phase 2: Behavioral Activation and Problem Solving. In phase 2, treatment sessions place an emphasis on behavioral activation and problem solving. Behavioral activation, such as increasing physical activity and engagement in pleasant and/or achievement-based activities, is a powerful way to improve mood in a relatively short period of time. Activities that might be relevant for Susan include scheduling phone calls to friends she has not spoken to for a period of time, attending mothers' group meetings, reengaging with her tennis, and

scheduling time to be alone with her husband. Action often precedes motivation, rather than the other way around, so clients must carry out the activities regardless of whether they feel they have the energy to do so, or whether they believe they are actually obtaining a sense of pleasure from the experiences. Susan may be encouraged to schedule and monitor activities that she may or may not find pleasurable but that nonetheless give her a sense of achievement (e.g., housework, paid work, caring for her child, cooking a meal). Monitoring these activities provides powerful evidence against helplessness and related negative thoughts such as “Nothing helps,” “I don’t achieve anything in my day,” and “I’m useless.” Other relevant variables to schedule may include sleep patterns, eating habits, diet, and exercise.

Depression often affects clients’ ability to make decisions. Structured problem solving (or active coping) provides a framework for clients to generate many alternative solutions to problems, consider the costs and benefits of each, select the solution with the most favorable balance of benefits to costs, develop an action plan (graded if necessary), apply the solution, and review the outcome. Clients are encouraged to attempt another solution if the outcome from the first attempt is not satisfactory.

Phase 3: Cognitive Restructuring. The third phase of treatment involves an increased emphasis on cognitive therapy techniques and behavioral experiments. The therapist provides psychoeducation about the cognitive model by explaining the link between thoughts and feelings. For example, Susan’s therapist might say: “Often we think that situations can directly cause us to feel a particular way. For example, if I’m driving along the road and a car cuts me off without indicating, I might feel angry. I’m also likely to believe that I feel angry *because* the car cut me off. But what about someone who feels anxious in the same situation? How could we explain the fact that the same situation can cause two very different emotions? If the situation directly caused how we felt, then we would expect it to be like a reflex, where the situation causes the same emotion in everyone. The cognitive model explains this by suggesting that there is something in between the situation and the emotions we feel—the way we *think* about the situation.”

To illustrate this point the therapist might then Socratically elicit thoughts from Susan that would result in anger (e.g., “How dare they! They shouldn’t do that to me!”), and then other thoughts that would elicit anxiety

(e.g., “They could’ve caused an accident and killed me!”). Socratic questioning is a pedagogical method whereby the individual guiding the discussion does not give information directly but asks a series of questions to engage the participant in arriving at the same information independently, in this case, interpretation of the event and the subsequent feelings arising from a particular interpretation.

Self-monitoring situations that are associated with low mood (or any intense or distressing emotion), along with corresponding negative automatic thoughts, can be a powerful way to teach clients the difference between thoughts and feelings and the functional relationship between them. Susan may benefit from learning about the ABC (activating event, beliefs, consequences) model and from the completion of thought diaries for homework. The therapist can reinforce the thought-emotion link during sessions by remaining vigilant to changes in affect during the session and asking what thoughts went through the client’s mind just prior to the change. Finally, clients sometimes state their thoughts as though they are immutable facts (e.g., “I’m such a failure for not being able to get a homemade dinner organized for my family every night like I used to”). In these instances it is useful to promote distancing from thoughts by rephrasing statements to reflect the fact that the situation triggered a thought in the client about herself (e.g., “Thinking about how you prepare dinner 5 nights a week and have had a ready-made dinner or takeout 2 nights now leads to the *thought* that you are a failure? And how does having the thought of being a failure lead you to feel?”).

Once the client has some experience successfully monitoring her thoughts and feelings, she is taught the process of thought challenging and disputation. The process of identifying and questioning negative automatic thoughts should be an opportunity for clients to realistically explore the evidence for and against their negative thoughts, alternative explanations of events, and the true probability and cost of their predictions. The therapist’s role is to facilitate this exploration through questioning (e.g., “So how did you figure that preparing meals 5 nights a week and ordering or buying ready-made meals 2 nights means that you are a failure?” “Would that evidence for your belief that you are a failure hold up in a court of law, or would the judge throw out the evidence that you have said shows you are fundamentally a failure?”).

Clients can be taught to identify unhelpful thinking styles in their negative automatic thoughts. While we all use unhelpful thinking styles from time to time,

people tend to use them more often when they are feeling strong emotions such as depression and anxiety. When clients become proficient at identifying these biases in their thinking, the labels can often be used as rapid shortcuts to the disputation process. For example, a client might say, “Oh, there I go catastrophizing again,” which she immediately understands to mean that she may be overestimating the probability or cost of a particular event. The goal of challenging negative automatic thoughts is to replace the thoughts with more helpful, realistic thoughts. Some common thinking styles are personalization, black-and-white thinking, labeling, overgeneralization, and catastrophizing.

Clients are encouraged to design behavioral experiments to directly test their negative automatic thoughts or assumptions about the self, others, and the world. One of Susan’s assumptions might be that if she tells a close friend about her depression then she will be rejected. When encouraged to consider how she would know she was being rejected, Susan might say that the friend would “Tell me to get over it, change the topic, and not contact me again.” The experiment would then require Susan to disclose her depression to a close friend and to pay close attention to the response. Before the experiment, the therapist acknowledges that if her predictions come to fruition, then her assumption is supported and should be maintained. However, if her friend does not respond in this way and instead is supportive, then Susan would be asked how this new information should be incorporated into her beliefs. Obviously the therapist would expect the predictions to be directly challenged, but broader principles should also be Socratically elicited about (1) the nature of her assumptions (i.e., unduly negative), (2) the discrepancy between the assumptions and outcomes, (3) the impact these negative assumptions have on emotions, and (4) how this new information could be used in the future (e.g., facilitate future thought challenging, not allowing initial negative assumptions to dictate behavioral avoidance).

Later treatment sessions are targeted toward the elicitation and realistic evaluation of personal assumptions and core beliefs. Thought challenging would typically begin at the level of negative automatic thoughts, with assumptions and core beliefs being challenged later in therapy to reduce vulnerability to relapse. The downward arrow technique can be used to identify core beliefs and assumptions. Once a client has identified an A (activating event) and B (belief or negative automatic thought), the therapist asks the client what that initial thought means about them, or what is bad about that. For instance, Susan might have the initial thought that “I’m not going to make a work deadline.” In response

to the question “What would be bad about that?” Susan might say “I’ll let people down.” The therapist would continue questioning to elicit assumptions and core beliefs.

Susan: “I’ll let people down.”
 Therapist: “What would be bad about that?”
 Susan: “If I disappoint people, they will think I’m not good enough.” (an assumption)
 Therapist: “What would that say about you?”
 Susan: “That I am a failure.” (a core belief about herself)

Susan might also report assumptions and core beliefs about other people.

Susan: “I’ll let people down.”
 Therapist: “What would be bad about that?”
 Susan: “My colleagues will be critical of me and not trust me again.” (an assumption)
 Therapist: “What does that say about other people?”
 Susan: “That other people are judgmental and critical” (a core belief about others)

Clients sometimes find this process distressing as they uncover some very negative core beliefs about themselves and others. However, intervening at this level of core belief can have a powerful effect on the client across a number of situations in which the assumptions and core beliefs are active.

Termination of therapy involves discussion of strategies for preventing relapse. A cognitive-behavioral therapist strives to maximize clients’ self-efficacy so that they can continue to be their own therapist following treatment. A self-management plan that documents early warning signs, situations that increase the client’s risk of relapse, strategies that could be employed to prevent future relapses, and coping statements the client could use to manage stressful situations is usually developed with the client. Finally, reviewing the outcome measures can be helpful for demonstrating progress and for setting new goals following therapy.

Bipolar Disorder

John is a 27-year-old man who has been unemployed since a recent admission to hospital. He previously worked in information technology support for a univer-

sity. He is single and has no children. John reported that he had experienced periods of low mood, reduced motivation, and loss of energy during his later childhood and adolescence. As he moved through high school and college, he would notice that these symptoms often worsened during times of stress, particularly when he was doing exams or completing assignments. He would become very concerned about failing and about letting people down at these times. Despite these problems, he completed his degree at college and had been managing his work responsibilities well. John is the youngest of three children. The family are close but have had difficulties communicating about John's bipolar illness.

John was first diagnosed with depression 2 years ago. He had been under some pressure at work and noticed that his mood was starting to change again. He felt very low and sad for most of the day, lost his appetite, started to lose weight, had a lot of difficulty getting to sleep at night, and would skip work to "make up" for lost sleep. John also felt sluggish and exhausted and couldn't concentrate as well when he was at work. He stopped his usual social activities, such as going out to see bands and playing soccer, and started to think about suicide. Within a couple of weeks, he had ingested weed killer in an attempt to kill himself and was admitted to hospital.

John recovered from this depressive episode after he was started on an SSRI antidepressant. He returned to work and resumed some of his regular social activities. However, about a year later he noticed his mood declining again and went to his GP to inquire about recommencing antidepressant treatment (which he had stopped after 6 months). He was prescribed a different antidepressant (mirtazapine). After he had been on this medicine for a few weeks, he started to feel dramatically better. He was energetic and euphoric but would feel very irritable if someone questioned him. He started to experience what he described as "extreme clarity of thought," which was accompanied by a sense of absolute certainty that he was right about how to solve world problems. He got less and less sleep and would wake up early to go on long bike rides or walks. Although he had always been fairly reserved and quiet, he became highly social, going out often, drinking more, and flirting with people he met in nightclubs.

After a couple of weeks of this behavior, John's family became very concerned and brought him to a hospital emergency department for assessment. He was later transferred to a locked psychiatric ward. He was diagnosed with bipolar disorder and commenced treatment with a mood-stabilizing medication (sodium valproate) and an atypical antipsychotic (olanzapine). He has continued to take his medications as prescribed

since his discharge from the hospital. His dose of olanzapine has been gradually reduced and will be ceased if he does not experience further psychotic symptoms over the next month.

Diagnosis and Symptoms

John participated in a clinical interview, which included administration of the MINI. His previous severe manic symptoms had disrupted his normal work and social functioning and were not the milder symptoms characteristic of hypomania. He reported that his mood was currently flat and his energy levels were low; however, these subsyndromal symptoms did not meet the criteria for a depressive episode. Consistent with his diagnosis at referral, he was diagnosed with bipolar disorder type I, and the specifier "in full remission" was applied.

John reported difficulty with anxiety throughout his life—he reported being a "shy" child and adolescent who did not make friends easily. He exhibited partial fulfillment of diagnostic criteria for social anxiety disorder but fell short of a full diagnosis. John had one severe panic attack a few years ago but did not meet criteria for a separate diagnosis of panic disorder.

He obtained a score of 0 at baseline assessment on the Altman Self-Rating Mania scale and a 9 on the Beck Depression Inventory-II.

Case Formulation

As with all cases of bipolar disorder the primary predisposing factor for onset of bipolar symptoms is likely to be a biological vulnerability to mood disorder. In John's case, this is indicated by a family history of mood disorder. John's mother has had treatment for depression, and he has a paternal aunt and cousin who have been treated for bipolar disorder. His long-standing history of shyness and low mood may also reflect a neurotic temperament or an introverted personality style, which may predispose someone to develop mood disorder (Goodwin & Jamison, 2007).

The main precipitating factor for his first diagnosed episode of mood disorder appears to have been work-related stress. His first manic episode may have been partly precipitated by the antidepressant medication he was prescribed.

A number of factors appear to be perpetuating John's current subsyndromal symptoms and perhaps making him more vulnerable to future episodes of mania or depression. Cognitively, he holds some unhelpful core beliefs and assumptions about himself and the future that are likely to make it harder for him to

cope with his current low mood and managing his illness in the long term.

Even in his current non-depressed mood state, John appears to hold a generally negative view of himself. He describes himself in terms that suggest core beliefs that he is ineffective and a failure. These core beliefs set him up to have particular difficulties at times when he is under pressure or when there is the possibility of failure, for example, when he experienced pressure at work. John also experienced a further loss of confidence after his hospitalization for mania. He had previously had an ideal of his future with respect to a permanent job, starting a relationship, and perhaps marriage and children. He now sees his future in much more uncertain terms and with possible future episodes of a recurring mood disorder. This belief about an uncertain future makes it harder for him to take action in regard to future goals, such as returning to work, as he no longer has an expectation that things will progress as planned.

Behavioral factors may be maintaining John's symptoms. He has not reestablished the regular social contacts he had before his first hospitalization. He only goes out to see bands once every couple of months and no longer participates in a weekly soccer game with friends. He sees his few closest friends, but not as often as he used to, and his irregular hours of sleep mean that he does not see his housemate regularly. This means that he experiences less pleasure in his life and that he has more time alone to ruminate about the changes in his life and the uncertain future.

Since experiencing a clinical episode of mania, John has become sensitized to any signs that his mood is becoming elevated. While this can be a helpful prevention strategy, he has become wary of too broad a range of early warning signs, including signs of normal, happy mood, such as feelings of enthusiasm. This serves to reinforce a pattern of avoiding pleasurable social activities in case they trigger a return to manic mood.

Physiological factors may also be perpetuating John's current low mood. John has a long-standing pattern of insomnia (even when his mood is normal), but this is exacerbated when he is in an episode of depression or mania. Since his discharge from the hospital, he has adopted a pattern of going to bed very late at night and sleeping until the early afternoon. There is some indication that this pattern of desynchrony between sleep and the daily dark-light cycle can perpetuate depression.

Treatment Plan

As noted above, there is evidence that psychoeducation and CBT can be effective in preventing relapse

from bipolar disorder. John would therefore be offered a treatment incorporating these elements—at our clinic this is generally provided in a group format from a manualized treatment program (Lim & Nathan, 2001). The group format has particular advantages in bipolar disorder treatment. Many of the people attending for treatment do not know people with bipolar disorder and have no other models for coping. The group sessions can be a profoundly destigmatizing experience, with many group members making comments like “I never thought everyone else would be so normal” after attending the first session. Other group members can also provide empathy, support, and models for coping. For John the group approach seems particularly appropriate, as he has been diagnosed relatively recently and has not yet been provided with a lot of information about bipolar disorder. He has also become socially isolated since his discharge from the hospital, so the group may be a way of easing him back into regular social contact.

The CCI bipolar group program runs for 12 weekly sessions of 2 hours' duration. It is delivered by a clinical psychologist, with a clinical pharmacist joining in to deliver a medication education session. Like all evidence-based adjunctive psychosocial treatment for bipolar disorder, the program provides psychoeducation about bipolar disorder and medication treatment. It also uses CBT techniques to help patients improve their skills for coping with their illness. The program is structured in three phases, and John's treatment plan will be described according to these phases of treatment.

Phase 1 (Sessions 1–3): Patient Education and Identification of Early Warning Signs. In the first phase of treatment, group participants are given information about their bipolar illness and their medications. John had previously ceased medications when he felt better, so information about the benefits of maintaining medication will be particularly relevant to him. He will also have the opportunity to ask detailed questions of the pharmacist who runs the medication education session. John may have questions about medication side effects or interactions and may benefit from suggestions about how to better manage his combination of medicines. Many people attending the group use this session as an impetus to discuss their concerns with their own treating doctor.

Participants are instructed in how to monitor their moods using a monthly mood chart. Ongoing mood monitoring will play an important role in helping John distinguish normal mood from manic mood. As he monitors his mood, he will be able to notice times when

his mood is positive or he feels happy and a manic episode does not result. He will also be able to notice any relationships between mood changes and changes in his life or routines.

Phase 2 (Sessions 4–9): Cognitive and Behavioral Strategies for Managing and Preventing Depression and Mania. In a group-based treatment, we do not have the opportunity for individual formulation. Instead, typical feedback loops are formulated for the group as a whole. For example, in session 4 we introduce behavioral strategies for managing depression, such as behavioral activation. This is presented in the same way it would be in the depression treatment described above, in terms of the depression cycle, where depressed mood leads to reduced motivation and energy, which leads to reduced activity levels, which leads to increased guilt and hopelessness, which exacerbates depressed mood. The group then reflects on ways they can break this cycle. The participants are prompted to focus on increasing activity in a balanced way. In this session, John might be encouraged to plan a balance of pleasurable activities (such as going to hear bands with friends) and achievement activities (such as paying bills or doing laundry) and then carry out his plan over the subsequent week.

We also introduce the cognitive therapy model in this phase of treatment. We introduce the model by asking group participants to note the connection between thoughts and feelings in a hypothetical situation. For example, we often use the situation of seeing a friend at a club and having them not respond to us. Over three sessions, participants learn the skills of identifying connections and recording their thoughts, emotions, and behaviors. They then learn to identify unhelpful thinking patterns characteristic of depression and to challenge and change unhelpful beliefs. For John, the most important beliefs to work on would be his self-stigmatizing beliefs about the implications of having bipolar disorder, his pessimistic beliefs about the future, and his fear of positive mood.

In group sessions, the example of depressed cognition is used to illustrate the cognitive strategies in the first instance, but many participants find that they are able to use the thought diaries and cognitive disputation techniques to address comorbid anxiety.

Cognitive strategies are applied in relation to hypomanic mood, but in a different way. Participants are encouraged to identify hypomanic thoughts ahead of time and prepare alternative balanced beliefs. Very often participants identify beliefs such as “I don’t need to sleep” or “I can stop taking my medication” that would clearly

put them at risk of further mood escalation. We emphasize that if mood has escalated beyond the point of hypomania, cognitive techniques are unlikely to be powerful enough to affect mood change without the help of adjustments to medication.

During this phase of treatment we spend time on the topic of sleep routine. Attendees are encouraged to keep a record of their sleep patterns over a week and to identify any problems they are having with their sleep routines. We discuss the importance of maintaining a regular sleep routine that is consistent with the day-night cycle (to enable normal social interactions with others and facilitate regular medication dosing, and because of the hypothesized links between circadian rhythm disruption and mood disturbance). This will be an especially relevant and important treatment component for John, who would be prompted to make some gradual changes in his sleep timing over the period he attends the course. For example, he may set a goal to go to bed half an hour earlier each week until he is able to get up in the morning to engage in the types of activities that he previously engaged in.

Phase 3 (Sessions 10–12): Problem Solving and Self-Management. In phase 1 of treatment, patients work through a life chart, identifying any links between psychosocial stressors (or medication noncompliance) and subsequent mood episodes. In phase 3 we return to this theme by conducting a survey of past, present, and anticipated life stressors for each group participant. We then teach the technique of structured problem solving (or active coping) to help people find a range of possible solutions to current problems, and to increase their confidence in addressing future problems. The life stressors and problems facing John are typical for the people attending our group program—particularly employment issues. The likely problems that John may tackle in this phase include returning to work or finding suitable alternative work, managing finances, and negotiating any conflicts that arise with his housemate or family.

In the final phase of treatment, we review and refine the action plans for responding to early warning signs of relapse that patients have been working on throughout the program. The aim of this action plan is to be as specific as possible about the early warning signs and the actions to take in response—for example, citing “stay in bed for an extra hour in the mornings” rather than “feel sad” as a depression early warning sign. We also work on identifying potential resources and sources of support, for example, community resources, family support, and personal qualities.

CLINICAL INNOVATIONS

Clinicians need to be aware of well-established developments in the field of affective disorders, as has been reviewed in this chapter. However, it is equally important to be cognizant of new innovations that are emerging.

Transdiagnostic Treatment for Depression

There has been recent interest in a transdiagnostic model of depression and anxiety, and we are investigating a treatment protocol based on this model at our site. The transdiagnostic approach departs from the prevailing “disordercentric” paradigm, which emphasizes matching specific treatments to specific diagnostic categories (Kring, 2008). Instead, the focus of treatment is on common maintaining processes across disorders.

Some of the impetus for a transdiagnostic model of depression and anxiety has come from the high comorbidity between anxiety and depression reported in many studies (Andrews, 1996; Mineka, Watson & Clark, 1998). Commonalities in dispositional factors, experience with uncontrollability, and unpredictability during childhood and studies examining the latent structures inherent in anxiety and depression have provided an impetus for this approach (McEvoy, Nathan, & Norton, 2009). Although the transdiagnostic approach lacks specificity, it may be a useful heuristic from which to base treatment applications.

Allen, McHugh, and Barlow (2008) recently outlined a unified protocol for emotional disorders derived from the emotion regulation literature. A transdiagnostic approach to treating unipolar depression and anxiety is an innovation that may be a valuable extension to Beck's standard CBT approach. A transdiagnostic protocol is responsive to the needs of clinical settings, where patient complexity and comorbidity is the norm. Service settings require efficiency, and it is more efficient to work on multiple conceptually related difficulties simultaneously than to treat them singularly in a linear fashion.

Translation of evidence-based protocols into clinical practice must be practical and correspond with treatment formulations required for clinically complex cases. In these respects, transdiagnostic approaches to treatment may have a number of advantages over diagnosis-specific protocols. For instance, they may facilitate more flexible application of treatment principles to all dysfunctional emotional experiences, not just those associated with the primary disorder. In this way, patients may be better equipped to simulta-

neously apply the strategies to comorbid conditions. Transdiagnostic approaches encourage a focus on common higher-order factors (e.g., negative affectivity), which may represent significant risk factors for relapse. Transdiagnostic approaches also reduce the number of treatment protocols required and therefore minimize training and acquisition costs. These costs may be significant obstacles to the dissemination of the vast array of evidence-based diagnosis-specific manuals. Transdiagnostic group therapy may also be preferable to diagnosis-specific groups for the practical reason that filling a diagnosis-specific group may take a considerable period of time in most clinics, resulting in longer treatment wait times.

The transdiagnostic approach has received preliminary support when used with individuals with depression. It has been evaluated in one controlled trial and at our site in effectiveness comparison studies (Craigie & Nathan, 2009; McEvoy & Nathan, 2007; Norton, Hayes, & Hope, 2004).

Mindfulness-Based Relapse Prevention for Depression

Earlier in this chapter it was suggested that affective conditions may be best viewed as chronic. Although individuals with depression are likely to successfully respond to pharmacological and psychological treatment—many to the point of recovery—recurrence and relapse rates are significant. Research has shown that individuals are changed by the experience of an affective episode and become sensitized to reexperiencing future episodes. Repeated associations between sad, depressed mood, and depressive cognitive schemata may result in microstructural changes at the cognitive and neuronal level (Teasdale, Segal, Williams, Ridgeway, Soulsby, & Lau, 2000). Mindfulness-based cognitive therapy (MBCT) has been evaluated as a prophylactic intervention for depression. MBCT seeks to alter cognitive-affective processing routes by changing the negative thinking activated by dysphoria. Instead of applying reality-based logic to challenge negative automatic thoughts, as is characteristic of standard cognitive therapy, MBCT encourages a detached, decentered relationship to depression-related thoughts and feelings. A multicenter trial showed that MBCT approximately halved rates of relapse and recurrence for those who had experienced more than two previous episodes of depression (Teasdale et al., 2000). MBCT may be a promising treatment in the prevention of relapse for those with recurrent depression (Williams, Russell, & Russell, 2008).

SUMMARY

The affective disorders are prevalent illnesses that are accompanied by a high rate of morbidity and social and economic burden. Standardized diagnostic interviews are easy and efficient to administer but require appropriate background and training. They are a sound means for arriving at valid diagnoses and the benefit of their use is underscored. For instance, bipolar depression can sometimes be misdiagnosed as unipolar depression, which is problematic given that one represents an indication and the other a contraindication for a commonly used pharmacotherapy strategy. While the etiology of depression and bipolar disorder is complex, it is generally agreed that it represents an interacting array of biological and psychosocial determinants. Neurochemistry, negative life events, cognitive processing, particular behavioral patterns, and interpersonal relations dominate leading accounts of onset, maintenance, and recurrence. When treating an individual with depression or bipolar disorder, one should base treatment decisions on clinical practice recommendations. Subsequent to this, specific elements should be guided by the idiographic clinical case formulation and by collaboration with the patient. Evidence-based treatments for depression are pharmacotherapy and the psychologically based interventions CBT and IPT. Pharmacotherapy is the leading evidence-based treatment in the acute and maintenance treatment of bipolar disorder. This is consistent with research that has demonstrated that bipolar disorder has a strong biological loading. Recent research has suggested that psychosocial interventions convey an additional prophylactic effect for bipolar disorder when combined with maintenance pharmacotherapy treatment. Recent innovations in depression treatment address gaps in our current intervention applications, such as how to best prevent relapse and what approaches might be useful in naturalistic clinical settings, where comorbid Axis I disorders and treatment time pressures are the norm.

Anxiety Disorders in Children and Adults: A Cognitive, Neurophysiological, and Genetic Characterization

Andrei C. Miu
Laura Visu-Petra

ADULT ANXIETY: CONCEPTUAL ISSUES RELEVANT TO THE CLINICIAN

Anxiety disorders are the most common category of mental disorders worldwide, placing a substantial burden on patients, their families, and society. The World Mental Health Survey Consortium reported 12-month prevalences of anxiety disorders that ranged from 2.4% in Shanghai, China, to 18.2% in the United States (Demyttenaere et al., 2004). The European Study of the Epidemiology of Mental Disorders has also investigated anxiety disorders' prevalence, risk factors, and burden and service use by mental patients in a sample of 213 million young and elderly adults from six European countries (i.e., Belgium, France, Germany, Italy, the Netherlands, and Spain). The data indicated that 12-month and lifetime prevalences of any anxiety disorder are 14.5% and 8.4% in the European population, respectively (Alonso & Lepine, 2007; see also Kessler, Chiu, Demler, Merikangas, & Walters, 2005).

Several factors contribute to the individual and social burden of anxiety disorders (Kessler, 2007). First, anxiety disorders are highly persistent; approximately 60%–70% of survey respondents with a lifetime anxiety disorder reported that their anxiety had been active within 6–12 months before the interview. Second, anxiety disorders are highly comorbid with other anxiety disorders and mood disorders. In addition, the lifetime prevalence of comorbid anxiety and depression has apparently increased in recent cohorts. Third, anxiety disorders are associated with substantial impairments in both productivity (e.g., work absenteeism, unemployment) and social roles (e.g., social isolation, marital disruption). Last but not least, anxiety disorders have an early age of onset (i.e., medians around 15 years) and they are associated with pervasive delays in seeking professional treatment.

The number of diagnostic categories for anxiety disorders has increased across the editions of the *Diagnostic and Statistical Manual of Mental Disorders*

(*DSM*). For instance, only 3 anxiety disorder categories existed in the *DSM-II* (American Psychiatric Association, 1968) as opposed to 12 categories in the *DSM-IV* (American Psychiatric Association, 1994). This increase in anxiety disorder categories has been viewed either as an effect of the greater precision in the classification of disorders, or, on the contrary, as evidence of the modest reliability of many diagnostic categories. Criticisms emphasize the increased empirical consideration of unique features of emotional disorders, made at the expense of shared or overlapping features that are equally relevant to prevention, etiology, and course of disorders (Andrews, 1996; Buckley, Michels, & Mackinnon, 2006). Although significant agreement on the presence of defining symptoms of *DSM* disorders has been empirically supported, considerable unreliability has in contrast been reported for categorical severity specifiers (i.e., mild/moderate/severe; Di Nardo, Moras, Barlow, Rapee, & Brown, 1993). This has led to the exclusion of severity specifiers for panic disorder (PD) and agoraphobia in *DSM-IV*. In addition, not only have some structured interviews (e.g., the lifetime version of the Anxiety Disorders Interview Schedule for *DSM-IV*; Di Nardo, Brown, & Barlow, 1994) been revised to make them consistent with *DSM-IV* criteria, but conceptual revisions have also been made to reflect the position that many features of emotional disorders operate on a continuum rather than in a categorical (i.e., presence/absence) mode. Therefore, these instruments can now inform diagnostic assessment of the key and associated features of a broad range of conditions, irrespective of whether a formal *DSM-IV* diagnosis is under consideration. Although assessments based on such structured interviews have acceptable to excellent reliability, the main difficulties arise when clinicians try to apply *DSM* categorical cutoffs to features rated on continuous dimensions (Brown, Di Nardo, Lehman, & Campbell, 2001). Disagreement on whether symptoms are sufficient in number, severity, or duration to meet *DSM-IV* diagnosis criteria is a common source of unreliability that suggests the necessity of revising the *DSM* by including dimensional rather than categorical criteria.

In addition to the limitations of the categorical approach to diagnostic assessment, the *DSM-IV* classification system has been confronted with a rapidly expanding body of literature identifying and linking genetic, neuroanatomical, neurophysiological, and cognitive differences in anxiety disorders. Multidisciplinary research in biological psychiatry and neuroimaging genetics has recently started to document so-called endophenotypes or intermediate phenotypes (Gottesman & Gould, 2003). Endophenotypes are subclasses of a diag-

nostic category, which are characterized by psychobiological markers that are more reliably associated with genetic variations (i.e., polymorphisms or mutations) than with the diagnosis category itself. For instance, endophenotypes of several anxiety disorders, characterized by preferential processing of threat (e.g., angry faces), increased amygdala activation, and reduced prefrontal control over amygdala activation to threat, as well as reduced response to selective serotonin (5-HT) reuptake inhibitors (SSRIs), have been associated with the short variant of a common polymorphism in the upstream regulatory region of the human 5-HT transporter gene (5-HTT; Canli & Lesch, 2007; see also Crisan et al., 2009). To date, research on endophenotypes of mental disease has amply demonstrated that the methodological and empirical advances in psychology, neuroscience, and interdisciplinary fields could and should influence the next generation of psychiatric diagnostic systems.

The *DSM-IV* is mostly based on cognitive and behavioral criteria, with the exception of a psychophysiological sign (i.e., exaggerated startle response) included in the diagnosis of post-traumatic stress disorder. Previous versions of the *DSM* included psychophysiological criteria (e.g., autonomic hyperarousal) for the diagnosis of other disorders such as generalized anxiety disorder (GAD). The reason for their exclusion was related to their lack of reliability, but it has been acknowledged that elimination of these objective criteria has made the distinction of generalized anxiety disorder from mood disorders, for instance, problematic (Brown, Barlow, & Liebowitz, 1994). Today, a wide array of more reliable psychophysiological methods is available, and methodological standards (e.g., Blumenthal, Cuthbert, Filion, Hackley, Lipp, & Van Boxtel, 2005; Fridlund & Cacioppo, 1986; Jennings, Berg, Hutcheson, Obrist, Porges, & Turpin, 1981; Malik et al., 1996; Picton et al., 2000; Pivik, Brogton, Coppola, Davidson, Fox, & Nuwer, 1993) limit procedural idiosyncrasies. Many would agree that psychology and neuroscience have developed enormously in the past decades and it is time that these advances were systematically taken into account in psychiatric diagnosis.

However, endophenotype research has only recently started to develop, and some of the reported associations between genetic variations and psychobiological phenotypes cut across current diagnostic categories. For instance, 5-HTT polymorphisms have been associated with both anxiety and mood disorders. Whether this situation suggests a radical revision of current diagnostic categories or the still insufficient specificity of endophenotypes is difficult to say at present. In addition to this issue, the practical validity of including psychobio-

logical diagnostic criteria that, however reliable, are still based on methods (e.g., functional neuroimaging) that are not widely available represents another apparent drawback in the systematic consideration of endophenotype research for diagnosis purposes. Nonetheless, the field is moving toward the investigation of interacting effects of multiple genetic polymorphisms on a still wider array of psychobiological measures, some of which (e.g., electroencephalogram-derived measures) are available and affordable (Miu, 2008). This warrants future improvements in the specificity of endophenotypes in relation to standard psychiatric diagnosis and the increasing influence of this research on psychiatric diagnosis systems.

The current diagnostic standards reflect the extensive research on pathogenetic cognitive factors that has been carried out in the last few decades. By employing experimental methods from cognitive and social psychology, psychophysiology, and more recently neuroscience, researchers have identified a host of cognitive and physiological differences thought to play critical roles in the etiology and pathogenesis of anxiety disorders. Under the influence of this type of research, theories of anxiety disorders have moved away from the stimulus-response models that dominated from the 1920s until the 1970s to information-processing models (H. J. Eysenck, 1976; Rachman, 1977). Behaviorist models viewed anxiety disorders as chronic attempts to avoid confrontation with fear-evoking cues or abnormal associations between stimuli and responses. For instance, phobia was described as an intense classically conditioned fear developed when an initially neutral stimulus (e.g., the white rat in the famous Little Albert case) was paired with a traumatic event (e.g., the frightening gong in the same case; Watson & Rayner, 1920). In line with learning theories (e.g., Wagner & Rescorla, 1972), conceptualizations of anxiety disorders acknowledged that the “signal value” of a stimulus as predictor of conditioning indicated the need for “informational models” and the refocalization of overly simplistic contiguity theories on the meaning of stimulus and response (Reiss, 1980).

The main assumption of cognitive models of anxiety disorders is that the emotional labeling of stimuli, particularly those that are perceived as aversive, plays a key role in the etiology, maintenance, and treatment of anxiety disorders (Eysenck, 1997; M. W. Eysenck, Derakshan, Santos, & Calvo, 2007; Mathews & Macleod, 1994, 2005; Williams, Mathews, & MacLeod, 1996). Cognitive research on anxiety has supported the view that anxiety disorders involve the dysregulation of otherwise adaptive emotions that have evolved to signal threat. Anxiety is a normal human emotion that can be characterized

by increased autonomic activity; subjective feelings of tension; cognitions involving fear and worry; and sometimes even behaviors like verbal incoherence, avoidance of anxious stimuli, motor immobility, or tremor (Kowalski, 2000). Based on animal and human studies, some researchers have distinguished anxiety from fear based on cognitive appraisal, overt behaviors, and/or neurobiological underpinnings. Whereas fear would be the emotional response to an identifiable threat, relying on amygdala activity, and associated with active behavioral avoidance, anxiety would instead be the emotional response to an unidentifiable or anticipated threat, relying on septo-hippocampal activity, and associated with active exploration for risk assessment or active avoidance (Blanchard & Blanchard, 1990; Gray & McNaughton, 2000; Lazarus, 1982).

Notwithstanding this distinction between anxiety and fear, Foa and Kozak (1986) were among the first to emphasize that emotional disorders “involve excessive response elements (e.g., avoidance, physiological activity) and resistance to modification” as well as “impairments in mechanisms for the processing of fear-relevant information” (p. 21). In other words, emotional disorders are based on altered “fear structures” or programs to escape dangers, revealing what threat means and which responses are appropriate, including the physiological activity that prepares the individual for escape (Foa & Kozak, 1986). In similar functionalist accounts of emotions, other authors have also argued that anxiety is part of a defensive mechanism against potential dangers (Calvo, Averó, & Miguel-Tobal, 2003; Keltner & Gross, 1999). By biasing cognitive (e.g., attention, interpretation, memory, decision making) and physiological processes (e.g., autonomic modulation of the heart), anxiety facilitates anticipatory threat detection and mobilizes resources before an actual harm occurs.

These effects or biases of anxiety on cognition and physiology were first described in relation to anxious states, sometimes called stress (for a distinction between stress and anxiety, see Lazarus, 1993), in healthy individuals. The individual differences approach to anxiety, which was pioneered by Freud (1924) and Cattell and Scheier (1958), has led to the subsequent psychometric delimitation of trait anxiety (TA), that is, a generalized and enduring predisposition of certain individuals to develop states of anxiety (Endler & Kocovski, 2001; Spielberger, 1985). Extensive research has shown in the past decades that TA involves a greater probability of developing anxious states to mild or ambiguous stimuli and/or upregulations of the intensity or duration of these states. Why is TA be important for the clinician? The medical model, as exemplified by the *DSM*, is of a

categorical nature and identifies clinical or pathological developments of anxiety based on a number of criteria. Cognitive psychologists have instead approached individual differences in the type of anxiety (i.e., subclinical) that does not qualify for an anxiety disorder diagnosis. Their extensive work has documented the similarity of cognitive and physiological biases in TA and anxiety disorders and has accredited the view that TA and other affective traits are important risk factors for emotional disorders (Brandes & Bienvenu, 2006; Lonigan, Vasey, Phillips, & Hazen, 2004; Mathews & MacLeod, 2005). The genetic, neuroanatomical, and neurophysiological similarities between TA and anxiety disorders, identified in recent years, have further supported this position (see Miu, Micalea, & Houser, 2008). According to current theories and research, the distinction between subclinical and clinical anxiety is a matter of degree rather than quality. In light of the foreseeable transition from categorical to continuous diagnosis criteria for anxiety disorders, understanding the variation of cognitive and physiological biases along subclinical and clinical dimensions of anxiety is extremely important for both researchers and clinicians. Therefore, this chapter will review cognitive and physiological biases identified in nonclinical participants, as well as in anxiety disorders patients; in the second part of the chapter, a developmental perspective upon the same dimensions will be provided.

COGNITIVE BIASES IN ANXIETY DISORDERS IN ADULTS

Difficulties in differentiating depression and anxiety based solely on subjective or self-report measures were an important aspect of the context that gave rise to the popularity of cognitive theories and experimental methods of assessing cognitive processing in anxiety in the 1980s. The high comorbidity of mood and anxiety disorders and high correlations between self-report scales assessing depressive and anxious symptoms made the quantitative justification of diagnostic decision difficult and suggested that discriminating between anxiety and depression strictly on the basis of emotional phenomenology was doomed to be problematic (R. Beck & Perkins, 2001). Cognitive theorists argued that cognitive content was different in anxiety and depression, with thoughts concerning physical and psychological threat in anxiety, and negative assessments of the self, the world, and the future in depression (e.g., A. T. Beck, 1976). In addition, the temporal focus of these cognitions differed in that anxious thoughts were

future oriented, whereas depressive thoughts were past oriented (Tellegen, 1985). In light of the inability of subjective measures to discriminate between anxiety and depression, it was also argued that more objective, experimental measures of cognitive processing could be used (Mathews & MacLeod, 1994). Once such measures were developed and refined, the search for cognitive biases in anxiety (tendencies to process information so as to favor certain types of emotional valence or meanings; Mathews & MacLeod, 2005) began to grow exponentially in mainstream psychology. These biases can characterize various stages of information processing by favoring the attentional selection of emotional over neutral stimuli; biasing the interpretation of ambiguous stimuli toward threatening meanings; increasing the availability of threat-related information in memory; and, last but not least, augmenting risk perception and risk taking in decision making.

Two main approaches to identifying cognitive biases in anxiety have been taken (Williams et al., 1996). The first investigated whether the tendency to selectively attend to emotional information facilitates performance on tasks that can benefit from the processing of such information. For instance, it was found that the visual and auditory thresholds to stimuli that are related to subjective concerns are indeed lower in patients with emotional disorders (e.g., Foa & McNally, 1986). The second approach has been to describe how the selective processing of emotional stimuli alters performance in tasks where this tendency would be disruptive. For instance, some of the most widely used assessments of this are the emotional Stroop, the attentional probe, the homophone interpretation, and the homograph relatedness judgment tasks.

In the emotional Stroop task, participants are presented with emotional and neutral words and they must rapidly name the color of the words while ignoring their meaning. This task was derived from the original color naming task described by Stroop in 1935, after it was observed that the latency of color naming increases under those circumstances that semantically prime the meaning of the words used in the task (e.g., self-referent words when the participant performs the task in front of a mirror; see Geller & Shaver, 1976). Thus the length of latency of naming the color of emotional words—an effect called emotional interference—provides an index of the tendency to selectively attend to emotional information in anxiety, which makes the task of ignoring the meaning of negatively valenced words particularly difficult in anxiety (Williams et al., 1996). In one of the first studies that tested this hypothesis, patients with clinical anxiety related to social or

physical threat displayed increased latencies in naming the color of threatening words, and the magnitude of this effect was higher for physically threatening words (e.g., “disease,” “cancer”) in patients with physical anxiety than for those with social anxiety (Mathews & MacLeod, 1985). Similar findings were reported in spider phobics, who displayed delayed color naming on spider-related words, but no difference in the latencies on other emotional words compared to healthy control participants (Kindt & Brosschot, 1997; Watts, McKenna, Sharrock, & Trezise, 1986). Similar effects have been replicated in a wide range of anxiety conditions, with a grand mean latency difference of 48 ms between emotional and non-emotional words (Williams et al., 1996). However, one of the observations that emerged early from emotional Stroop research on anxiety indicated that performance of this task is disrupted particularly when the words are related to the central theme of patients’ anxiety: rape-related words for rape victims (Foa, Feske, Murdock, Kozak, & McCarthy, 1991); social threat for patients with social phobia (Hope, Rapee, Heimberg, & Dombeck, 1990; Mogg, Bradley, Dixon, Fisher, Twelftree, & McWilliams, 2000); catastrophe themes and physical threat for PD patients (McNally, Riemann, Louro, Lukach, & Kim, 1992); and Vietnam trauma themes for Vietnam veterans with PTSD (McNally, Kaspi, Riemann, & Zeitlin, 1990).

Another issue that emerged from this kind of research is related to whether the emotional interference characterizes automatic or strategic modes of information processing. Automatic information processing is independent from attentional resources and insensitive to voluntary control, whereas strategic information processing denotes the involvement of both attentional mechanisms and voluntary control (McNally, 1995; Wells & Mathews, 1994). This issue has been related to the specificity of cognitive biases in anxiety and depression. According to mainstream theories, processing is biased toward selective processing of threat at automatic stages of information processing (e.g., detection and preattentional orientation) in anxiety, before that information has entered conscious awareness, whereas depression involves biased processing of emotionally negative information at strategic stages of information processing (e.g., elaboration of the meaning), after that information has entered conscious awareness (Mathews & MacLeod, 1986). Alternatively, anxiety is characterized by cognitive biases in attention (e.g., assessed with emotional Stroop tasks), and depression is characterized by biased memory (MacLeod, 1990; Mathews, 1990).

Several approaches have been developed to test the prediction of preattentional biases in the emotional

Stroop task. First, a comparison between supraliminally and subliminally presented words was employed (Mogg, Bradley, Williams, & Mathews, 1993). In the subliminal condition, emotional and neutral words were presented for brief intervals (e.g., 1 ms), followed by the supraliminal presentation of meaningless strings of letters (i.e., mask) that remained on the screen until participants responded. The main finding was that the patients with GAD, but not those with major depression, displayed significant emotional interference effects in both the supraliminal and subliminal conditions. One of the implications of these results concerned the utility of cognitive therapy in reducing the unconscious cognitive biases toward the processing of threat in anxiety, an issue that has been theoretically and empirically addressed by cognitive therapists. Similar findings were reported in a study that investigated the effects of TA, state anxiety, and relevance of emotional words to the stressor (i.e., a proximal exam) on emotional Stroop performance (MacLeod & Rutherford, 1992). Elevated state anxiety increased emotional interference effects on all subliminal threatening words in high-TA participants, and it decreased these effects in low-TA participants. In addition, elevated state anxiety increased interference effects on emotional words unrelated to the exam, but it decreased emotional interference on exam-related words—these effects were independent of TA. These results were taken to indicate that elevated state anxiety increases the automatic tendency to selectively process threat in high-TA but not low-TA participants. The former are thus characterized by an “unstable feed forward system” that intensifies automatic cognitive biases under stress, whereas the latter “enjoy the benefits of a homeostatic emotional system” that will automatically screen out threatening information in order to reduce the level of state anxiety (MacLeod & Rutherford, 1992, p. 489). In the supraliminal condition, high-TA participants displayed a strategic tendency to avoid negatively valenced emotional information related to the source of state anxiety, an effect that they shared with low-TA participants. This indicated strategic control over cognitive biases in high-TA participants. The conclusion was that “both high TA normals under stress, and clinically anxious patients, may display an equivalent automatic pattern of processing selectivity, favoring threat related information, but that high TA normals alone, unlike clinical patients, may be able to reduce the emotional impact of this automatic bias by strategically imposing the opposite pattern of selectivity on the processing of stress relevant emotional information” (MacLeod & Rutherford, 1992, p. 490).

A different approach to the selectivity of attention in anxiety involved a “separated Stroop task” in which

distracter words and target patches of color were presented above one another, and participants were instructed to name the color of the patch and ignore anything else on the card (Fox, 1993). The words were both names of colors (i.e., non-emotional distracters) that were either congruent or incongruent with the color of the simultaneously presented patch and words differing in emotional tone, some of which were thus emotional distracters. The results indicated that high-TA participants displayed longer color-naming latencies both when the patches were presented with threatening emotional distracters and when the color name distracters were presented. It was concluded that this indicates the general difficulty that high-TA participants have ignoring distracting information, which raises the issue of the specificity of attentional biases to threat-related information rather than distracters in general. A similar conclusion was reached for GAD patients (Mathews, May, Mogg, & Eysenck, 1990). However, these studies have not disputed the preattentive bias toward the processing of threat, which has been replicated (e.g., MacLeod & Hagan, 1992; for negative results in clinical anxiety, see Buckley, Blanchard, & Hickling, 2002; Gotlib, Kasch, Traill, Joormann, Arnow, & Johnson, 2004). Indeed, in an emotional Stroop analog with images of faces—faces are viewed as more salient signals of social and emotional information than words—it has been shown that TA influenced emotional interference to masked, but not supraliminal fearful faces, and it also predicted activation of the basolateral part of the amygdala during the processing of the former emotional stimuli (Etkin et al., 2004). Potential explanations for the occasional attentional bias in depression, but not anxiety, are related to comorbid anxiety in depressed patients, or the prolonged exposure conditions (e.g., Gotlib et al., 2004), which allows for the development of the strategic tendency of depressed participants to look longer at stimuli related to their sad mood, as well as for the early attention to threat in anxious patients to be superseded by later avoidance (Mathews & Macleod, 2005). The brief presentation of words eliminated the attentional bias toward negative words (e.g., “hopeless,” “misery”) that was found in conditions involving naturally occurring or laboratory-induced sad moods, and fairly long (e.g., > 500 ms) exposure of words (Bradley, Mogg, & Lee, 1997). In contrast, the masked presentation of words did not affect the attentional bias toward threatening words in anxiety, irrespective of the sad mood. Therefore, the duration of stimulus exposure and the comorbidity of anxiety and depression may explain some of the negative results in studies of emo-

tional Stroop. It has also been suggested that methods such as the attentional probe task may be more sensitive than the emotional Stroop to the attentional bias that characterizes anxiety.

The attentional probe task involves the brief presentation of two words or pictures that differ in emotional tone, in symmetrical locations above and below a central fixation point. These stimuli are followed after some 500 ms by a small visual probe that appears in the location of either word. As soon as they detect the probe, participants are supposed to push the button that corresponds to the part of the screen in which the probe appeared (MacLeod, Mathews, & Tata, 1986). As a reflection of their tendency to allocate attention to the spatial location in which a threatening stimulus appeared, faster responses to probes presented in that location are expected in participants with anxiety. Both high-TA participants and patients with clinical anxiety display speeded detection of the probes that appear in the spatial location where threatening stimuli had appeared (Koster, Crombez, Van Damme, Verschuere, & de Houwer, 2004; Wilson & MacLeod, 2003). A series of experiments offered evidence that high TA is associated with faster detection of probes that occurred in the same location as masked threatening faces, but not happy faces (Mogg & Bradley, 1999). Moreover, the magnitude of this effect increased if the faces were subliminally presented in the left half of the screen, which probably restricted their processing to the right hemisphere. This observation is in line with the documented role of the right hemisphere in emotional surveillance and the anterior activation asymmetry theory of affective style (e.g., Davidson, 2002).

The attentional probe has been particularly useful in approaching the mechanisms supporting the selective allocation of visual attention toward the locus of threatening information. Individual differences in attentional bias have been explained in terms of the level of stimulus threat (i.e., “urgency threshold”; Mathews & MacLeod, 2005, p. 171) that marks the transition from active avoidance to active attention. In a study in which location was cued with neutral or angry faces, low levels of stimulus threat were associated with increased latencies to detecting the probe (avoidance), whereas high levels of stimulus threat were associated with faster detection (vigilance) of the probe (Wilson & MacLeod, 2003). In addition, the urgency threshold that marked the transition from avoidance to vigilance was lower in anxious than in non-anxious participants.

Another mechanism supporting the attentional bias in anxiety may be related to difficulty in disengaging from the threatening information, instead of selective

attention drawn to the locus of the threatening stimuli (Fox, Russo, Bowles, & Dutton, 2001). In other words, does anxiety modulate how threat draws or holds attention? Two studies using modified attentional probe tasks approached this issue. The first study cued a single spatial location using threatening or non-threatening stimuli and hypothesized that the fastened detection of probes that appeared in the threat-cued location (i.e., so-called valid trials) would indicate facilitated engagement with threat, whereas slowed detection of probes that appeared opposite to threat-cued locations (i.e., invalid trials) would indicate facilitated disengagement from threat (Derryberry & Reed, 2002). Anxious participants were slower in probe detection on invalid threat-cued trials, but not faster than non-anxious participants in valid threat-cued trials. This seems to support the hypothesis of facilitated disengagement from threat in the attentional bias characteristic of anxiety. However, a follow-up study cued a spatial location using the gaze direction of a centrally presented fearful face. Both the faster detection of the probe in valid trials and its slowed detection in invalid trials were increased in anxious compared to non-anxious participants (Mathews, Fox, Yiend, & Calder, 2003). Therefore, effects of anxiety on neither the engagement nor disengagement from threat can be discarded. Disengagement difficulties may predominate when threatening stimuli are encountered incidentally (Mathews & MacLeod, 2005).

The homophone interpretation task investigates homophones having both threatening and non-threatening meanings (e.g., “guilt-gilt,” “die-dye”), but a distinct spelling for each meaning (M.W. Eysenck, MacLeod, & Mathews, 1987). The underlying assumption is that anxiety biases the interpretation of homophones in favor of the threatening meaning. Comparing the percentage of spellings that corresponded to the more threatening of the two meanings of homophones, it was found that patients with GAD, even those who had been recovered for 6 months, chose the threatening meaning significantly more often than control participants (M.W. Eysenck et. al, 1987). Therefore, GAD patients tend to interpret ambiguous information in a threatening way. Another study used the same task to test whether state anxiety influences the degree to which contextual cues (e.g., the word “death” or “hair” presented on a screen as participants hear the homophone [di]) influence the spelling of the word corresponding to the emotional or neutral meaning of homophones (Blanchette & Richards, 2003). The results indicated that state anxiety induced when participants are lead to believe that their performance is videotaped increased the probability that participants would choose to spell the homophone

according to its emotional meaning when the emotional context (e.g., “death” in the example above) was presented. This effect was replicated even when the emotional context was presented subliminally, supporting the existence of an automatic bias of anxiety on interpretation of homophones.

In the homograph relatedness judgment task, homographs offering both threatening and non-threatening interpretations (e.g., “stroke,” “conviction”) are first presented on a screen. Some 500 ms later, a pair of words is displayed, only one of which is semantically associated with one of the meanings of the previously presented homograph. Participants have to choose the word in the pair that is related to the homograph that was previously presented, and it is expected that anxiety accelerates responses when the associate is related to the threatening meaning of the homograph (Wilson, MacLeod, Mathews, & Rutherford, 2006).

Both the homophone interpretation task and the homograph relatedness judgment task are measures of the online interpretations of ambiguous stimuli made at the time of their encounter. Other studies have used offline measures of interpretation biases concerning inferences on ambiguous stimuli presented at other times. For instance, one study used emotional and neutral short passages related to social or evaluative situations, followed by a questionnaire that required the interpretation of factual details presented in the target texts (Brendle & Wenzel, 2004). Particularly when the passages were self-relevant, socially anxious individuals made fewer positive and more negative interpretations of details in the texts. These offline measures have generally shown that anxiety is associated with biases toward negative interpretations of ambiguous stimuli (Mathews & MacLeod, 2005). For instance, patients with PD interpret descriptions of physical sensations as symptoms of catastrophic disease (Richards, Austin, & Alvarenga, 2001), whereas patients with social phobia predict disastrous outcomes for social situations (Stopa & Clark, 2000).

The evidence in favor of memory biases in anxiety disorders is mixed. In order to extend the predictions of automatic information-processing biases in anxiety and strategic-processing biases in depression, many studies have investigated both implicit and explicit memory. Implicit memory involves indirect tests (i.e., without specific instructions for participants to search their memory) of information that is learned as an unintended effect of previous experience. For instance, in a common test of implicit memory, participants are asked to complete a list of word stems with the first word that comes to mind, therefore without any specific referral

to the study list that was previously presented. Priming is an implicit memory effect that refers to the increased probability that the word stems will be completed with words that appeared in the study list. Explicit memory, on the other hand, refers to consciously controlled retrieval of previously learned information, and it is tested by free recall or recognition.

According to an early theory (Williams, Watts, MacLeod, & Mathews, 1988), anxiety disorders are characterized by orientation to threat during automatic stages of information processing, which is expected to increase priming of this information, and avoidance of further elaboration on threat in strategic stages of information processing, which is expected to decrease explicit retrieval of this information. This pattern of bias may contribute to pathogenesis of anxiety disorders by preventing habituation to threatening stimuli. This model was consistent with the finding of poorer memory for threatening than nonthreatening information (Mogg, Mathews, & Weinman, 1987). Actually, GAD patients recognized fewer threat words and more nonthreat words than controls in this study, which suggested that they actively avoid elaborative processing of threat and therefore have poorer recall of such information. Similar studies investigated implicit and explicit memory biases in relation to TA, and with the exception of three early studies (Nugent & Mineka, 1994; Reidy & Richards, 1997a, 1997b), they found no memory bias (Bradley, Mogg, & Williams, 1994; Brendle & Wenzel, 2004; Calvo et al., 2003; Dalgleish, 1994; Harrison & Turpin, 2003; Oldenburg, Lundh, & Kivistö, 2002; Reidy, 2004; Richards & French, 1991). Another study that compared GAD patients with healthy volunteers on tests of explicit and implicit memory (Mathews, Mogg, May, & Eysenck, 1989) found increased priming in the clinical group, but no differences in a cued-recall task. Due to its inclusion instruction (i.e., "Complete the stems with words presented in the study list *or* words that first come into mind"), cued recall is taken to rely on both automatic and controlled processes of memory (see Toth, Reinhold, & Jacoby, 1994).

Although studies do not generally support explicit memory biases in GAD or social phobia, there is consistent evidence for explicit memory biases in PD, and some degree of support for explicit memory biases in PTSD and obsessive-compulsive disorder (OCD; for review, see Coles & Heimberg, 2002). Several studies indicated increased free recall and recognition of threatening passages and words in PD, in comparison to corresponding neutral and positive stimuli (Nunn, Stevenson, & Whalan, 1984; Cloitre & Liebowitz, 1991). This is consistent with clinical observations of the tendency of

PD patients to report vivid memories of previous threatening experiences and sensations. Fewer studies have investigated implicit memory in PD, and the positive findings of memory biases have been limited to certain experimental conditions (e.g., low noise), and they have not been replicated (see Coles & Heimberg, 2002). Better success has been reported in studies of explicit memory in PTSD, a disorder that involves intrusive and repetitive reexperiences of the trauma. Vietnam veterans with PTSD recalled more threatening than nonthreatening words (Vrana, Roodman, & Beckham, 1995), and in comparison to controls, adult survivors of childhood sexual abuse with PTSD recalled fewer of the positive and neutral words that they were instructed to remember (McNally, Metzger, Lasko, Clancy, & Pitman, 1998). Moreover, PTSD patients also displayed increased false recall of words associated with those in the study list, which may suggest their increased susceptibility to false memories (Zoellner, Foa, Brigidi, & Przeworski, 2000). Similarly, theories of OCD have implicated memory deficits since the beginning of the 20th century by explaining checking rituals based on impaired retrospective memory. Indeed, OCD patients recalled more negative words, which they had been instructed to forget in a directed forgetting task, than controls (Wilhelm, McNally, Baer, & Florin, 1996). However, as concluded by Coles and Heimberg (2002), the evidence for memory biases in PTSD and OCD is sparse and far from definitive.

One of the issues that the authors of this review have identified as crucial to the development of this field is related to the nature of the encoding tasks. Procedures that encourage the shallow processing of the study material are unlikely to find evidence for explicit memory biases. Using a task in which emotional "oddballs" appeared in lists of neutral words, one of our studies found that TA did not affect the recall of threatening "oddballs" but did influence the recall of adjacent neutral stimuli (Miu, Heilman, Opre, & Miclea, 2005). Therefore, although the recall of threatening stimuli did not differ, it retroactively interfered with the ongoing encoding of the immediately preceding neutral stimuli in high-TA participants. This increased "emotion-induced retrograde amnesia" associated with TA was found in free but not cued recall, and it was not influenced by the depth of processing. The emotion-induced retrograde amnesia has been replicated in anxiety-prone participants with a common functional polymorphism in the regulatory region of 5-HTT gene (Strange, Kroes, Roiser, Tan, & Dolan, 2008).

Recent research has increased the focus on decision-making biases in anxiety, and it has been argued that these biases play a crucial pathogenetic role in

anxiety disorders (Ernst & Paulus, 2005; Miu et al., 2008; Paulus, 2007). Decision making is a key component of human cognition and behavior, involving the ability to choose between possible outcomes associated with uncertain benefits and penalties (van Leijenhorst, Crone, & Bunge, 2006). One of the best-documented effects of anxiety on decision making involves risk perception and risk avoidance. An early study used a risk evaluation task in which participants were supposed to evaluate the probability and personal utility of events described in several passages (Stober, 1997). High TA was associated with increased probabilities and negative utilities (i.e., costs) when the events were negative, and decreased probabilities and utilities (i.e., benefits) when the events were positive. These results suggest that anxiety is associated with a pessimistic bias in the perception of risk and chance. Similar findings have been reported for acute stress disorder, a condition that most often develops into persistent PTSD (Harvey & Bryant, 1998). Compared with trauma-exposed controls without acute stress disorder, acute stress disorder patients overestimated the probability of somatic and social harm, as well as the adverse effects of such negative external events (Smith & Bryant, 2000). Both high-TA individuals and patients with anxiety disorders also report or display decreased risk taking in subjective or behavioral measures of this bias. In one well-known experimental risk-taking task (i.e., balloon analog risk task), participants can earn financial rewards by pumping balloons presented on a screen—different balloons have variable explosion points, and once a balloon explodes, the money deposited for pumping that balloon is lost. Anxiety is associated with reduced mean pumps per unexploded balloon, which indicates risk aversion (Maner et al., 2007). In addition, anxious individuals have an increased susceptibility to a decision-making error known as the framing bias, which is induced when two otherwise equivalent alternatives are phrased differently (e.g., participants have to decide whether to keep or gamble a sum of money within “gain frames” announcing that “provided an initial sum of 50 dollars, you gain 20 dollars,” and “loss frames” described as “provided an initial sum of 50 dollars, you loose 30 dollars”). Kahneman and Tversky (1984) found that framing biases decision making by inducing risk avoidance in the gain frames, and risk taking in the loss frame. Recent studies have indicated that these biases are increased in anxiety, which indicates decreased rationality in this type of decision making (Lauriola & Levin, 2001). Increased intolerance for uncertainty is another characteristic of decision making in anxiety, which has also been implicated in the pathogenesis of GAD (Krain

et al., 2008). Intolerance for uncertainty correlated with amygdala and prefrontal activation in a sample of GAD adolescents, which would explain why anxiety biases the assessment and formation of preferences among possible options (Ernst & Paulus, 2005; Krain et al., 2008).

Anxiety has been associated with hyperarousal or increased interoception (i.e., homeostatic sensing of the internal state of the body), as well as increased top-down modulation of interoceptive signals through biased attention and interpretation. Accordingly, anxious individuals may show “an altered pattern of aversive somatic markers during the assessment stage of decision making . . . , as well as during the experience of outcome” (Ernst & Paulus, 2005, p. 602). We recently used an Iowa gambling task and psychophysiological correlates of emotional response to find this exact pattern in participants selected for extreme TA (Miu, Heilman, & Houser, 2008). The Iowa gambling task (IGT) simulates real-life decision making in the way it factors uncertainty of premises and outcomes, as well as reward and punishment (Bechara, Damasio, Damasio, & Anderson, 1994). It measures the degree to which individuals learn to choose small immediate gains associated in the long term with smaller losses over large immediate gains associated in the long term with yet larger losses. High TA was associated with a pattern of increased anticipatory skin conductance prior to advantageous trials, increased heart-rate deceleration to punishment, and impaired decision making. These results clearly indicate that high TA is associated with defective modulation of somatic signals, coupled with disrupted discrimination of advantageous and disadvantageous choices in decision-making tasks involving learning from emotional cues. The new field of neuroeconomics promotes multidisciplinary approaches to decision-making biases, and therefore further progress in the investigation of anxiety-related biases in risk perception, risk taking, intolerance to uncertainty, assessment of alternatives, and evaluation and experience of outcomes is warranted (Miu et al., 2008; Paulus, 2007; see also Rahman, Sahakian, Cardinal, Rogers, & Robbins, 2001).

After this brief review of evidence of cognitive biases in anxiety disorders, the reader is now prepared to have a critical, empirically driven perspective on cognitive models of anxiety disorders. Remember that these models and the experimental approaches to assessing cognitive biases have grown in popularity in light of the difficulties in differentiating anxiety and depression based on self-report measures. An important issue that has been broached by cognitive models of anxiety is

related to the stage of information processing in which biases that are specific to anxiety act. Perhaps the best-known theory addressing this issue is that of A.T. Beck and Clark (1997), which incorporates previous experimental and theoretical work (A.T. Beck, Emery, & Greenberg, 1985; Mathews & MacLeod, 1994; McNally, 1995). According to this theory, the erroneous or biased interpretation of stimuli as threatening, as well as the individual's underestimation of coping resources and rescue possibilities in the environment, is a core feature of anxiety disorders. Clinical anxiety is viewed as an exaggerated perception of danger that differs only in degree from subclinical anxiety. This theory also acknowledges that anxiety involves a pattern of cognitive, behavioral, subjective, and physiological changes that arise from a three-stage information-processing sequence.

The first stage, or the orienting mode, involves the use of automatic processing to detect stimuli and assign an initial processing priority through the allocation of attentional resources. The recognition of emotional valence (i.e., positive or pleasant, negative or unpleasant, and neutral) and personal relevance are the typical outputs of this stage of processing. Anxiety disorders are characterized by a biased orienting mode, which involves preferential processing of negatively valenced, personally relevant stimuli.

The second stage, called immediate preparation, relies on the activation of a primal mode defined as a cluster of schemata. Such a schema is the threat mode, a pattern of cognitive, behavioral, and physiological responses that seeks to minimize danger and maximize safety. The threat mode involves autonomic arousal, behavioral mobilization and inhibition, and constriction of cognitive processing onto the threatening stimulus, as well as the production of repetitive and automatic thoughts and images involving threat and danger, and feelings of fear. This stage of processing relies on a combination of automatic and strategic processes that create a conscious impression of threat. This impression is based on processing that may occur outside awareness. However, the primary threat appraisal or semantic analysis of the stimulus begins at this stage. Processing at this stage is rigid and dichotomous and associated with intolerance to uncertainty and ambiguity. It results in preferential processing of negatively valenced information at the expense of positively valenced stimuli, and activation of negative automatic thoughts with themes of threat and danger.

The third stage of processing, secondary elaboration, involves a metacognitive mode and rests on strategic processes. Individuals reflect on their anxious thoughts, feelings, and sensations, which were activated

in the primal mode. A type of contextualized processing takes over and consequently schemata representing the current concerns and personal issues of the individual become activated. This stage of information processing implements a secondary appraisal process in which individuals evaluate the availability and effectiveness of their coping resources in relation to the perceived threat. It can result in the escalation or decline of anxiety, as well as in a subsidence of anxiety due to escape or avoidance behaviors prompted by the primal mode. Worry and the search for safety signals are characteristic of this stage of strategic elaboration on perceived threat.

Considering that information-processing biases arise in automatic stages of information processing, it has been argued that cognitive, verbally mediated therapy would be ineffective in influencing them. While acknowledging that verbal mediation is a necessary but not sufficient component of any anxiety therapy, A.T. Beck and Clark (1997) have nonetheless argued that teaching patients a strategy that maximizes elaboration and reflection on their threat-related cognitions can be beneficial. Indeed, a study that compared Beck's cognitive-behavioral therapy (CBT) and behavior therapy (i.e., learning to control symptoms through relaxation, reducing avoidance of threatening stimuli through graded exposure, building confidence through reengagement in pleasurable and rewarding activities) indicated that the former type of therapy is more effective than the latter in GAD, with improvements in most of the measures of anxiety, depression, and cognitions that were taken (Butler, Fennell, Robson, & Gelder, 1991). Other studies have shown that cognitive-behavioral therapy in the test-retest interval reduces interference of masked threat words in emotional Stroop tasks, and the degree of this reduction correlates with reductions of anxious thoughts that persist at follow-up (Mathews, Mogg, Kentish, & Eysenck, 1995; Mogg, Bradley, Millar, & White, 1995; but see also Devineni, Blanchard, Hickling, & Buckley, 2004). Even treatment with SSRIs reduces interpretive biases in a homophone interpretation task, and this effect on cognitive biases correlates with reductions of self-reported anxiety (Mogg, Baldwin, Brodrick, & Bradley, 2004). Therefore cognitive biases reflect relief from anxiety symptoms.

The direct test of the hypothesis that cognitive biases play a causal role in anxiety disorders has come from studies that manipulated cognitive biases and measured their impact on psychopathology. These studies have only recently begun, but their results are already promising. For instance, a four-session training

to interpret descriptions of ambiguous events in an increasingly positive manner reduced TA (Mathews, Ridgeway, Cook, & Yiend, 2007). Using parallel versions of the attentional probe task, in which probes always appear in the location of the threat or neutral word, another important study indicated that the training with these probes led to faster or slower detection of the probes that replaced threat or nonthreat words, respectively. Moreover, the latter bias predicted lower increases in negative mood in a subsequent stressful anagram task (MacLeod, Rutherford, Campbell, Ebsworthy, & Holker, 2002). Similar trainings designed to induce attentional avoidance of threat in high-TA students predicted decreased state anxiety in response to an impending examination (Mathews & MacLeod, 2002; MacLeod, 2008). The reduction of interpretive biases of ambiguous passages also induced decreased anxiety reactivity to a stressful video (Wilson et al., 2006). These data provide strong support for causal contributions of cognitive biases to anxiety. The extension of these studies to clinical anxiety is warranted. Testing the impact of cognitive bias reduction on a wider array of anxiety symptoms (e.g., subjective, behavioral, and physiological) will consolidate the clinical potential of these experimental interventions. Indeed, it may turn out that “cognitive processing bias may be the common pathway underlying reductions in vulnerability to emotional disorders, whether due to medication, cognitive training, or conventional psychological treatment” (Mathews & MacLeod, 2005, p. 187).

However, investigations of the biased automatic processing of negatively valenced stimuli (i.e., the valence hypothesis) and specificity of themes in self-reported automatic thoughts of anxiety patients (i.e., the cognitive content hypothesis) have been challenged. An emotional Stroop task with masked and unmasked presentation of the stimuli has been used to investigate the two hypotheses in PTSD and PD (Buckley et al., 2002). The results indicated no bias in color naming of threat words in the masked version of the emotional Stroop task. PTSD but not PD patients only showed interference effects on negatively valenced stimuli in the unmasked versions of the task. In contrast, the cognitive content hypothesis was supported in this study, with PD patients showing increased interference effects on unmasked disorder-specific threatening stimuli. Other studies have challenged even the cognitive content hypothesis. A meta-analysis of 13 studies indicated that depression and anxious cognitive content share most of their variance, with an average correlation across studies of .66 (R. Beck & Perkins, 2001).

Whereas the empirical support for the important contribution of cognitive biases to anxiety disorders is extensive and sound, the studies that reported negative findings suggest that these contributions may differ between anxiety disorders. In addition, they also highlight the possibility that anxiety disorders arise from interactions among different representational systems (Daggleish, 2004). Specific cognitive models emphasizing the role of catastrophic misinterpretation of bodily sensations and panic self-efficacy in PD (Casey, Oei, & Newcombe, 2004; D. M. Clark, 1986), increased self-directed attention triggered by social situations, and decreased attention to positive external cues in social anxiety have thus been developed for each of the anxiety disorders (for review, see Mathews & MacLeod, 2005). These models explain why these patients anticipate negative reactions from others and fail to effectively encode actual social feedback (Alden & Taylor, 2004; D. M. Clark & Wells, 1995; Rapee & Heimberg, 1997), disorganized memory representation induced by extreme emotions experienced at the time of trauma, in interaction with premorbid intelligence in PTSD (Brewin & Holmes, 2003; Buckley, Blanchard, & Neill, 2000; Daggleish, 2004), and negative beliefs about worry or metacognitive “worry about worry” in GAD (Borkovec & Roemer, 1995). However, even in regard to these specific models, it has been argued that the incorporation of research on the impact of early learning histories, temperamental vulnerabilities, personality risk markers, and inefficient emotion regulation strategies is long overdue (Amstadter, 2008; Brandes & Bienvenu, 2006; Gross, 1998, 2002; Mineka & Zimbarg, 2006). The consideration of these factors has started to inform strategies for prevention of anxiety disorders (Bienvenu & Ginsburg, 2007; Feldner, Zvolensky, Babson, Leen-Feldner, & Schmidt, 2008; Feldner, Zvolensky, & Schmidt, 2004).

GENETIC AND PHYSIOLOGICAL MARKERS IN ADULT ANXIETY DISORDERS

The recent empirical and methodological integration of human genetics and neuroscience has started to result in major advances in our understanding of the biology of human mental health and disease (Hariri & Lewis, 2006). A wide array of methods and approaches has been applied in multidisciplinary investigations of anxiety disorders, including twin and adoption studies, genetic linkage and genetic association studies, and electrophysiological and functional neuroimaging studies.

The genetic contributions to a trait or disease have been investigated in three main types of research

designs pertaining to behavioral and molecular genetics. First, twin and adoption studies compare monozygotic and dizygotic twins raised together and apart to determine what part of the variance of a trait or disease can be attributed to additive and non-additive genetic effects, as well as shared (family-wide) and non-shared (individual-specific) parts of the environment (Plomin, DeFries, McClearn, & McGuffin, 2008). For instance, a twin study indicated moderate (31 %) genetic effects, minimal shared environmental effects (15 %), and substantial non-shared environmental effects (54 %) for TA (Lau, Eley, & Stevenson, 2006). Therefore, most of the variance in TA is accounted for by genetic influences (e.g., polymorphisms in the 5-HTT gene) and family-wide factors such as dysfunctional early parent-child relationships, neighborhood conditions, and the socioeconomic status of the parents (Carlson & Sroufe, 1995; Caspi, Taylor, Moffitt, & Plomin, 2000; Miech, Caspi, Moffitt, Wright, & Silva, 1999). Studies comparing the prevalence of panic among relatives of PD probands and the relatives of controls have consistently indicated high familial loading of this disorder. For instance, a meta-analysis of 13 such studies found that the lifetime prevalence of panic was 10.7% among the relatives of PD probands, compared to 1.4% among the relatives of healthy controls—this gives a relative risk of 6.8 for PD (Gorwood, Feingold, & Ades, 1999). Indeed, twin studies of PD estimated heritability of PD to be as high as 44 %, which places this disorder at the top of heritable anxiety disorders (Kendler, Walters, Neale, Kessler, Heath, & Eaves, 1995). Family and twin studies of specific phobia have reported that the relative risk for phobia is 3.1, and the estimated heritability is 35 % (Fyer, Mannuzza, Chapman, Martin, & Kleon, 1995; Kendler, Neale, Kessler, Heath, & Eaves, 1992a). There are few such studies on the other anxiety disorders, and the results have been rather inconsistent (for review, see Merikangas & Pine, 2002).

The other two approaches to determining the genetic influence on a certain trait or disease are genetic linkage and genetic association studies. The former first determines if a specific DNA sequence from a certain chromosome is related to a trait or disease and then involves sequencing the genes in that portion of the chromosome in order to identify the variations (e.g., functional mutations or polymorphisms) that modify the functions of those genes in a manner that significantly influences the trait or disease under study. Genetic polymorphisms occur in >1% of a population, and they are thus more likely than less frequent mutations to influence the variance of a trait or disease in that population. For instance, the linkages of PD to

mutations in adrenergic receptor or gamma-aminobutyric acid receptor A loci have been investigated, and the results were negative (Schmidt, Zoega, & Crowe, 1993; Wang, Crowe, & Noyes, 1992). Even genomic surveys that used 600 markers with known chromosomal locations (i.e., they serve as probes for the chromosomal location of the DNA sequence of interest) found no genetic linkage in PD. This lack of success in genetic linkage of anxiety disorders is probably related to factors such as their etiologic and phenotypic heterogeneity, the lack of reliable diagnostic thresholds, and their comorbidity with other forms of psychopathology (Merikangas & Pine, 2008). On the other hand, genetic association studies have identified several genetic polymorphisms that influence the behavioral and neurophysiological phenotype of anxiety. In these studies, the variants of genes that are known to influence a trait or disease are identified, and the frequency of alleles in samples with or without that trait is determined.

A growing body of literature has investigated the influence of certain polymorphisms on various phenotypic aspects that are relevant to disease. One of the goals of these studies has been to focus on functional polymorphisms of the genes related to the neurotransmitter system that is targeted by the standard medication for a disease (e.g., SSRIs). Consequently, many genetic association studies have investigated genetic polymorphisms in the genes encoding the synthesizing and catabolizing enzymes, pre- and postsynaptic receptors, and molecules controlling intracellular trafficking and extracellular transport of 5-HT. For instance, 5-HTT is the initial molecular target of SSRIs that have antidepressant and anxiolytic functions. Its gene (SLC6A4) is located on chromosome 17q11-12 and encodes a transmembrane protein involved in the reuptake of 5-HT in the presynaptic neuron following its exocytosis to the synaptic cleft (Lesch, Wolozin, Murphy, & Reiderer, 1993; Ramamoorthy et al., 1993). We know of two polymorphic regions of 5-HTT: a 44-bp insertion/deletion polymorphism (5-HTTLPR, where LPR stands for “linked polymorphic region”) in the promoter region of the gene, and a variable number of tandem repeats in the second intron of the gene (VNTR-in2; Hranilovic et al., 2004; Lesch et al., 1996). 5-HTTLPR alleles are commonly composed of either 14 or 16 repeated elements (Heils et al., 1996). The latter, called a long (L) allele, is more than twice as active as the former, called a short (S) allele, in terms of 5-HTT expression and uptake of 5-HT by platelets (Lesch et al., 1996). Lesch et al.’s landmark study also reported that 5-HTTLPR accounts for 7%–9% of the heritable variance of individual differences in anxiety, with the S homozygotes

displaying increased TA. Further studies have shown that S homozygotes display better therapeutic response to SSRIs, hyperactivation of the amygdala during the processing of threatening stimuli (e.g., fearful faces), and reduced volume of the gray matter in the anterior cingulate cortex and amygdala (Hariri et al., 2002; Heinz et al., 2007; Pezawas et al., 2005). Studies on the influence of 5-HTTLPR on autonomic responses have offered inconclusive results to date (Schmidt, Storey, Greenberg, Santiago, Li, & Murphy, 2000).

Recent research has identified a single nucleotide polymorphism within the L allele of 5-HTTLPR itself, and the observation that one of the alleles (L_C) is low functioning in comparison to the L_A allele (Hu et al., 2006) has led to more reliable findings in regard to the response to SSRIs among individuals with social anxiety (Stein, Seedat, & Gelernter, 2006). It has been suggested that the effects of low-functioning alleles of 5-HTTLPR develop particularly in individuals who are systematically exposed to stressors (Gunthert, Conner, Armeli, Tennen, Covault, & Kranzler, 2007). Almost a quarter of the individuals who have a stressful job and report symptoms of anxiety or depression are carriers of the S allele of 5-HTTLPR (Caspi et al., 2003). Indeed, the risk of GAD is almost double for individuals who have stressful jobs (Melchior, Caspi, Milne, Danese, Poulton, & Moffitt, 2007), of whom those carrying a low-functioning allele of 5-HTTLPR may be the most exposed. In addition, the VNTR-in 2 polymorphism in 5-HTT gene has been shown to contribute to anxiety disorders (e.g., OCD) and other psychiatric conditions with a major stress component (Ogilvie et al., 1996; Wendland et al., 2008). The alleles of this polymorphism contain 9, 10 (i.e., S alleles), or 12 (i.e., L alleles) copies of 16- or 17-bp repeats in the second intron of the 5-HTT gene. It is likely that additional sources of variation in this and other genes (e.g., tryptophan hydroxylase, 5-HT receptors 1A and 2A) will be uncovered, and these may also prove to influence the 5-HT regulation of the stress response and its contribution to anxiety disorders. In light of the estimated 100 such polymorphisms that contribute to the variance of complex traits and polygenic diseases, the current focus is on studying epistatic interactions between these and other genetic polymorphisms (Brown & Hariri, 2006; Canli & Lesch, 2007; also see Table 13.1). The great potential of these studies comes in part from the wide diversity of measures by which the anxious phenotype can be related to genetic polymorphisms.

Electrophysiological measures have been extensively used to characterize the phenotype associated with anxiety disorders. These measures index auto-

nomic and central nervous system correlates of emotional responses. It has long been held that exaggerated fear responses are common to all anxiety disorders. With the success of animal models in documenting the involvement of the amygdala and adjacent structures in fear (see Davis, 1998; LeDoux, 2000), one of the most extensively used psychophysiological measures has been the fear-potentiated startle. There are at least two reasons for the popularity of this measure: it relies on the activation of the amygdala, and it can be measured in both animals and humans. The human startle reflex is a series of unconditioned motor responses (i.e., forward thrusting of the head, a descending flexor wave reaction extending through the trunk and knees) to an intense and unexpected stimulus (Landis & Hunt, 1939). In humans, a brief (e.g., 40 ms) and loud (i.e., 90–115 dBA) burst of white noise (i.e., the startle probe) is presented, and the eye blink, the most consistent component of the startle pattern (Grillon, 2002), is recorded in order to measure the latency and magnitude of the startle reflex. The fear-potentiated startle refers to the increased latency and magnitude of the startle reflex during aversive states, such as those elicited by the anticipation of an electric shock. Whereas the startle reflex relies on a simple reflex arc (i.e., cochlear root neurons, neurons in the nucleus reticularis pontis caudalis, and motoneurons in the spinal cord), the fear-potentiated startle relies on an additional projection from the central nucleus of the amygdala to the nucleus reticularis pontis caudalis (Grillon, 2002). In light of the demonstration that negatively valenced stimuli (e.g., affective pictures) presented before the startle probe potentiates startle response (Lang, Bradley, & Cuthbert, 1990), the potentiation of the startle reflex has been used as an objective index of the perceived aversiveness of a stimulus and the cognitive bias toward threat. Pictures of spiders for spider phobics (de Jong, Visser, & Meckelback, 1996), anticipation of public speaking for individuals with social anxiety (Cornwell, Johnson, Berardi, & Grillon, 2005), emotional imagery for individuals with PD (Cuthbert, Drobos, Patrick, & Lang, 1994), and verbal threat or administration of the probes in a dark environment for PTSD patients (Grillon, Morgan, Davis, & Southwick, 1998a, 1998b) have been shown to potentiate the startle reflex. Therefore, elevated fear-potentiated startle seems to support the hyperactivity of the amygdala in anxiety disorders (see Cuthbert, Lang, Strauss, Drobos, Patrick, & Bradley, 2003; Grillon, 2002; Lang, 1995).

Psychophysiological measures of autonomic functions have also been useful in describing anxiety disorders. They have been used to test the assumption

GENE	LOCATION	PROTEIN AND FUNCTION	POLYMORPHISM(S)	RELEVANT EFFECTS	REFERENCES*
<i>TPH-1</i>	Chromosome 11	Tryptophan hydroxylase 1 (TPH1); hydroxylation of l-tryptophan to 5-hydroxytryptophan	SNPs: A-779C (<i>U</i> , upper allele) and A-779C (<i>L</i> , lower allele)	<i>U</i> carriers show higher scores of anger-related traits	(Nielsen, Dean, & Goldman, 1992; Rujescu et al., 2002)
<i>TPH-2</i>	Chromosome 12	Tryptophan hydroxylase 2 (TPH2): same as TPH1, but specific to the brain	SNPs: G-703T (rs4570625)	<i>T</i> variant correlates with trait anxiety; it influences amygdala reactivity; its frequency is higher in patients with personality disorders	(Brown et al., 2005; Canli, Congdon, Gutknecht, Constable, & Lesch, 2005; Gutknecht et al., 2007; Herrmann et al., 2007)
<i>5-HT1A</i>	Chromosome 5	5-HT1A receptor: autoreceptor on presynaptic soma, and postsynaptic receptor for 5-HT	27 known SNPs: e.g., C-1019G (rs6295); C-1018G; Ile-28Val (rs1799921); Arg-219Leu (rs1800044); Gly-22Ser (rs1799920); Pro-16Leu; Gly272asp	C-1019G: carriers of the G allele have higher scores of anxiety and neuroticism	(Strobel et al., 2003; Zetzsche et al., 2008)
<i>5-HT2A</i>	Chromosome 13	5-HT2A receptor: G-protein coupled postsynaptic receptor for 5-HT	SNPs: G-1438A (rs6311); T-102C (rs6313); His-452Tyr (rs6314)	C homozygotes display more anger and aggression-related behaviors; negative correlation with trait anxiety	(Giegling, Hartmann, Moller, & Rujescu, 2006; Rybakowski et al., 2006)
<i>MAO-A</i>	Chromosome X	Monoamine oxidase A (MAO-A): primary catabolizing enzyme for synaptic 5-HT, noradrenalin, and dopamine	VNTR in the upstream promoter region: 3.5 or 4 repeat elements (high-expressing MAOA-H variant) vs. 3 or 5 repeats (low-expressing MAOA-L variant)	Male carriers of the low expressing variant show dysregulated amygdala activation and increased functional coupling with ventromedial prefrontal cortex	(Buckholtz et al., 2008; Gross & Hen, 2004)

<i>COMT</i>	Chromosome 22	Catechol-O-methyl-transferase (COMT): postsynaptic catabolizing enzyme for catecholamines (i.e., dopamine, adrenalin, noradrenalin)	SNP: Val-158Met (rs4680)	Val/Val genotype is associated with 3-4 times higher COMT activity compared to Met/Met; the former genotype is associated with higher amygdala and prefrontal activation to emotional faces in panic disorder patients	(Baekken, Skorpen, Stordal, Zwart, & Hagen, 2008; Domschke et al., 2008; Lotta et al., 1995; Wray et al., 2008)
<i>BDNF</i>	Chromosome 11	Brain-derived neurotrophic factor (BDNF): neurotrophic factor that contributes to neural development and plasticity	SNP: Val66Met	Met/Met is associated with lower neuroticism	(Hunnerkopf, Strobel, Gutknecht, Brocke, & Lesch, 2007)

Notes: The references are only illustrative. SNP = single nucleotide polymorphism; VNTR = variable-number tandem repeat.

of tonic or phasic hyperarousal in anxiety. Heart-rate variability (HRV) is a non-invasive electrocardiographic index of the autonomic control of the heart, which has been studied extensively in anxiety disorders (Cohen, Matar, Kaplan, & Kotler, 1999; Friedman & Thayer, 1998; Friedman, Thayer, Borkovec, Tyrrell, Johnson, & Columbo, 1993; Gorman & Sloan, 2000). HRV reflects oscillations in the interval between consecutive heartbeats, and it results from the dynamic or homeostatic interaction of sympathetic and parasympathetic (vagal) inputs to the sinoatrial node (Braun, Kowallik, Freking, Hader, Kniffki, & Meesmann, 1998; Robinson, Epstein, Beiser, & Braunwald, 1966). To date, the relationships between sympathetic and vagal influences on the heart are not completely understood (Eckberg, 1997). However, a reduction in the parasympathetic innervation is considered to leave the heart exposed to unopposed stimulation by the sympathetic nervous system, and consequently vulnerable to ventricular arrhythmia and sudden death (Gorman & Sloan, 2000). The analysis in the frequency domain involves the distribution of oscillations in at least two frequency bands and the determination of power in each of these bands. Power in the high-frequency band ($\sim 0.15\text{--}0.4$ Hz in adults) has been associated with respiratory sinus arrhythmia and is considered to reflect vagal modulation of the heart, whereas power in the low-frequency band ($\sim 0.05\text{--}0.15$ Hz) probably reflects a complex interplay between sympathetic and vagal influences (Eckberg, 1997; Kingwell, Thompson, Kaye, McPherson, Jennings, & Esler, 1994; Malik et al., 1996). Reduced HRV in anxiety and affective disorders is empirically supported. For instance, several studies have reported that HRV is reduced in patients with panic disorder (Klein, Cnaani, Harel, Braun, & Ben-Haim, 1995; Sullivan, Kent, Kleber, Martinez, Yeragani, & Gorman, 2004; Yeragani et al., 1991) and even the children of patients with panic disorder (Srinivasan, Ashok, Vaz, & Yeragani, 2002). Patients who reported frequent severe panic attacks showed reduced HRV in a variety of laboratory conditions (e.g., quiet rest, shock avoidance, face immersion, isoproterenol infusions) and a dominant sympathetic control of heart rate associated with reduced vagal tone (Friedman et al., 1993; Yeragani, Pohl, Srinivasan, Balon, Ramesh, & Berchou, 1995). High TA is also associated with reduced HRV, decreased vagal tone, and higher vagal withdrawal during mental stress (Bleil, Gianaros, Jennings, Flory, & Manuck, 2008; Miu, Heilman, & Micalea, 2008). Also, low HRV predicts exaggerated startle responses to threat of shock in both healthy participants selected for TA and PD patients (Melzig, Weike, Hamm, & Thayer, 2008).

Various other psychophysiological indices have shown their utility in distinguishing between anxiety

disorders. For instance, GAD and PD patients may report similar levels of anxiety symptoms under stressful conditions (i.e., a mental arithmetic task and images of severe panic attacks), but the latter, or at least a subgroup, can be distinguished by lower levels of end-tidal CO_2 at baseline, which seem to suggest a chronic state of relative hypocapnia (Hegel & Ferguson, 1997). On the other hand, GAD patients seem to be more sensitive to changes in physiological arousal, since it was shown that they can detect significantly more of changes in skin conductance fluctuations (i.e., resulting from the sympathetic stimulation of sweat gland secretion) during a signal detection task (Andor, Gerlach, & Rist, 2008). In comparison to PD, PTSD patients display decreased parasympathetic regulation of the heart (i.e., respiratory sinus arrhythmia) and increased sympathetic activity (i.e., skin conductance amplitude) at baseline, but blunted electrodermal responses under threat-of-shock conditions (Blechert, Michael, Grossman, Lajtman, & Wilhelm, 2007). Indeed, a recent meta-analysis indicated increased resting heart rate, which may reflect reduced parasympathetic control over the heart and slow skin conductance habituation to startling probes, as well as larger facial muscle and heart-rate responses to idiographic trauma cues (Pole, 2007; see also Lindauer, van Meijel, Jalink, Olff, Carlier, & Gersons, 2006).

Psychophysiological recordings during exposure to stressful conditions have also provided interesting insight into phobia. Blood pressure increases more in anxiety and anger than in happy states, and it has been suggested that these emotional effects may be facilitated in individuals with more labile blood pressure (James, Yee, Harshfield, Blank, & Pickering, 1986). The case study of a patient with PD with agoraphobia indicated that systolic blood pressure during exposure to the anxiogenic situation (i.e., traveling on a chairlift) strongly (and positively) correlates with stress (Lewis & Drewett, 2006). Other studies show that high TA is associated with increased heart rate during preparation of a to-be-evaluated speech, and the same is true for social phobia (Gonzalez-Bono, Moya-Albiol, Salvador, Carrillo, Ricarte, & Gomez-Amor, 2002; Hofmann, Newman, Ehlers, & Roth, 1995; but see Mauss, Wilhelm, & Gross, 2003).

Electroencephalography (EEG) recordings and functional neuroimaging have been used extensively to study central neurophysiological markers of anxiety disorders. The frontal lateralization of EEG power in the alpha band (i.e., 8–13 Hz) has been related to emotional valence, motivation, and affective style (Davidson, 2003; Harmon-Jones, 2003; Heller, 1993). Decreases in EEG alpha power suggest increases of cortical activity induced by the thalamic suppression of alpha waves (Larson et al.,

1998). Greater right-to-left frontal EEG alpha power reflects processing of positive valence and approach-related motivational tendencies, whereas greater right-to-left frontal EEG alpha power reflects processing of negative valence and withdrawal-related motivational tendencies. There is much controversy regarding the degree to which the frontal asymmetry of EEG alpha power reflects emotional valence (the valence-arousal hypothesis) or motivational direction (the approach-withdrawal hypothesis). However, the correlation of the right resting frontal EEG alpha power and a negative affective style characterized by reduced emotional resilience is extensively supported. For instance, people with high TA (Petrusello & Landers, 1994), social phobia (Davidson, Marshall, Tomarken, & Henriques, 2000), and PD (Wiedemann, Pauli, Dengler, Lutzenberger, Birbaumer, & Buchkremer, 1999) and even children whose parents have social phobia (Campbell, Schmidt, Santesso, Van Ameringen, Mancini, & Oakman, 2007) show increased right-lateralized frontal EEG alpha power, and a recent meta-analysis confirmed moderate effects of anxiety on this EEG index (Thibodeau, Jorgensen, & Kim, 2006). Benzodiazepines reverse the pattern of frontal activity in monkeys, and the degree to which the greater relative right frontal activation changes into greater relative left frontal activation correlates with reductions in behavioral signs of anxiety (Davidson, Kalin, & Shelton, 1992). An optical neuroimaging study confirmed the relationship between anxiety and frontal activation asymmetry. During a state of anticipatory anxiety, the levels of oxyhemoglobin, which indicates a local rise in energy demands, increased more in the right than in the left medial prefrontal cortex. This increase was positively correlated with individual differences in anxiety (Morinaga et al., 2007).

Following Heller's suggestion (Heller, Nitschke, Nitschke, Etienne, & Miller, 1997; but see Mathersul, Williams, Hopkinson, & Kemp, 2008) that subtypes of anxiety are associated with different patterns of cerebral activation asymmetry (i.e., anxious arousal is associated with greater right posterior activation whereas anxious apprehension is associated with greater left anterior activation), it has been reported that arousal symptoms correlate with right-sided parietal activation in PTSD female Vietnam War nurse veterans (Metzger et al., 2004). Other EEG-derived measures have also been applied in studies of anxiety disorders. For instance, frontal midline theta activity, which has been shown to reflect feelings of relief from anxiety during mental tasks, correlates with reductions in anxiety symptoms in GAD (Suetsugi et al., 2000).

Given the fact that TA is substantially genetic in nature, one would expect it to be associated with differ-

ences in brain structure and function. Indeed, an early magnetic resonance spectroscopy study indicated that TA is associated with higher concentrations of the excitatory neurotransmitter precursor N-acetylaspartate in the orbitofrontal cortex (Grachev & Apkarian, 2000). Subsequent neuroimaging work supported the view that TA is associated with structural and functional differences in the neural structures related to emotion and emotion regulation, particularly in the temporal and frontal lobe. For instance, a recent magnetic resonance imaging (MRI) study showed that both women and men with high TA displayed reduced volume of the right hippocampus; however, only the women also had reduced volume of the left anterior prefrontal cortex (Yamasue et al., 2008). TA has also been negatively correlated with resting regional cerebral blood flow in the left parahippocampal gyrus and orbitoinsular junction, as well as other regions in the frontal, temporal, and parietal cortex (Sugiura et al., 2000). Finally, functional MRI studies have indicated that activity in frontal and medial temporal lobe structures also varies as a function of TA in cognitive tasks. TA was correlated with anterior cingulate response to emotionally positive stimuli (Canli, Amin, Haas, Omura, & Constable, 2004; for discussion, see Hamann & Harenski, 2004). Also, TA predicted activation of the basolateral amygdala to subliminally processed fearful faces (Etkin et al., 2004; see also Mujica-Parodi et al., 2009).

Amygdala hyperactivity during symptom provocation or negative emotional processing has been supported by functional neuroimaging studies in individuals with PTSD, social anxiety, specific phobia, OCD, and PD. A recent meta-analysis that included functional neuroimaging studies in individuals with PTSD, social anxiety, and specific phobia analyzed the shared and specific neural activity in these conditions and tested whether data across studies support the view that limbic dysregulation is associated with prefrontal dysfunctions (Etkin & Wager, 2007). In various emotional processing conditions (e.g., emotional Stroop, reading of emotional passages, viewing of emotional pictures or emotional videos), patients with all three anxiety disorders displayed amygdala hyperactivity. The ventromedial prefrontal cortex, rostral anterior cingulate cortex, and thalamus were hypoactivated in PTSD and the activation of the former also correlated negatively with symptom severity in PTSD, but not social anxiety or phobia. Compared with PTSD, the hyperactivation of the amygdala was more specific to phobia, whereas the hyperactivation of the insula was common to phobia and social anxiety. This meta-analysis also found evidence of consistent correlation between ventromedial prefrontal cortex hypoactivity and amygdala and insula

hyperactivity. It was concluded that all three disorders involve exaggerated activation of the amygdala, but in addition, PTSD also involves dysfunctions of the neural circuits associated with emotion regulation (see Etkin, Egner, Peraza, Kandel, & Hirsch, 2006; Goldin, McRae, Ramel, & Gross, 2008). Although functional neuroimaging studies on clinical populations are limited by typical small sample sizes, heterogeneity in task design (e.g., block, single trial, or event-related designs), and patient characteristics (e.g., inherent comorbidity), meta-analyses allow us to determine the reliability of effects. This way, the identification of neural markers may help describe the mechanisms that are shared and specific to anxiety disorders, which will likely affect diagnosis, nosology, and development of new therapies in the future.

CHILDHOOD ANXIETY: EARLY VULNERABILITY MARKERS

Developmental studies have contributed to a life span perspective on the psychopathology of anxiety disorders. These disorders have typically been shown to begin early in life (Gregory, Caspi, Moffitt, Koenen, Eley, & Poulton, 2007; Kessler, Berglund, Demler, Jin, & Walters, 2005; Pine, Cohen, & Gurley, Brook, & Ma, 1998). Current approaches to pediatric anxiety (e.g., Pine, 2007; Vasey & Dadds, 2001) combine information from genetics, affective neuroscience, and clinical work, generating an information-processing framework to characterize cognitive functioning in this disorder. Such an approach attempts to reveal the mechanisms through which an early vulnerability status, combined with specific environmental experiences, can modify the neural circuitry underlying fear-related behaviors throughout development.

This section attempts to provide a state-of-the-art overview of current findings regarding early vulnerability signs for development of anxiety disorders in the clinical but also in the nonclinical at-risk population. The main findings suggest the fluidity of anxiety disorders throughout the life span, underscoring the need for a developmental perspective. A second premise is that vulnerability markers at different levels (genetic, neurological, behavioral) are connected to families of disorders rather than to a specific outcome (Pine, 2007). The following multilevel analysis of the vulnerability factors identified during childhood and adolescence will complement the preceding section on adult risk factors with the dynamics of anxiety disorders throughout development. The overall aim is to assist the clini-

cian (viewed as a scientist-practitioner) in identifying early (often cumulative) risk factors for development of anxiety disorders, and to inform developmentally tuned prevention and intervention programs.

EPIDEMIOLOGY AND DIAGNOSTIC FEATURES

The early manifestations of anxiety disorders partially overlap with a typical pattern of fear development during childhood and adolescence. This normative ontogenetic parade (Scarr & Salapatek, 1970) consists of separation anxiety (6–22 months); stranger anxiety (6–24 months); fear of unfamiliar peers (20–29 months); fears of animals, darkness, and imaginary entities (2–6 years); performance anxiety (6–12 years); fear of physical harm and injury (8–16 years); and social anxiety (12–18 years; Egger & Angold, 2006; Pennington, 2002). An exaggeration of such typical concerns in terms of intensity or persistence beyond these age intervals indicates a potential anxiety disorder. Thus, there is a parallel ontogenetic scenario in the onset of specific subtypes of clinical anxiety: separation anxiety and specific phobias in middle childhood (ages 7–9), over-anxious disorder in late childhood (10–13 years), social phobia in middle adolescence (15–16 years), and panic attacks in late adolescence (17–18 years), as reviewed by Merikangas and Pine (2002).

The classification of childhood anxiety disorders mimics the adult symptoms clustering in *DSM-IV* (American Psychiatric Association, 1994) and the tenth edition of the *International Classification of Diseases* (World Health Organization, 1992). According to *DSM IV*, separation anxiety disorder (SAD) is the only condition that is specifically classified as a “disorder first diagnosed in infancy, childhood or adolescence.” An overview of diagnostic criteria and prevalence information for childhood anxiety disorders is beyond the scope of this chapter, but we refer the reader to comprehensive reviews by Cartwright-Hatton, McNicol, and Doubleday (2006); Schniering, Hudson, and Rapee (2000); Weems and Stickle (2005); and Vallance and Garralda (2008). Egger and Angold (2006) present an overview of the scarce research regarding preschool anxiety disorders and their assessment and treatment.

Under the general label of “childhood anxiety disorders” we refer to the *DSM-IV* nosological categories of SAD, panic disorder, selective mutism, OCD, GAD, social phobia, specific phobias, and PTSD. However, most of the developmental research has been conducted using diagnostic criteria from the *DSM-III* (American

Psychiatric Association, 1980), which has been shown to be relatively consistent (Kendall & Warman, 1996) with the newer categories in the *DSM-IV* (one essential change in the latter is the requirement of evidence of impairment for an anxiety disorder to be diagnosed). Therefore, at certain points in this chapter, we will refer to categories from the previous version of the *DSM*, such as overanxious disorder (consistent with GAD from *DSM-IV*) and avoidant disorder (relatively consistent with the newer social phobia in the *DSM-IV*; Kendall & Warman, 1996).

An important issue in delineating these clinical categories is their discriminant validity, namely, the degree to which they can be differentiated from each other and from other disorders of childhood. We believe that anxiety in children and adolescents is best conceptualized as falling along a clinical continuum (see the description of typical fears above), with accentuated intensity and persistence of symptoms as well as increasing life distress as a marker for the diagnosis of anxiety disorders. For some anxiety disorders (e.g., overanxious disorder, overanxious disorder), it has been difficult to disentangle clinical from nonclinical controls in terms of anxiety-provoking situations, distress, or subjective level of cognitive competence (Beidel, Silverman, & Hammond-Laurence, 1996). The introduction of the new category of GAD in the *DSM-IV* has revealed a better discriminative power, considering the larger number of worries in clinically anxious children (Tracey, Chorpita, Douban, & Barlow, 1997). However, at this first level of delineating clinical from nonclinical variations populations, the existing screening and diagnosis tools ensure a reasonably consistent differentiation (see Schniering et al., 2000). In terms of the prevalence of overall anxiety disorders, most studies have only targeted children over 6 years of age (and mostly over 11), with very heterogeneous results. The comprehensive review by Cartwright-Hatton et al. (2006) suggests a prevalence ranging from 3% (Ford, Goodman, & Meltzer, 2003) to 24% (Kroes et al., 2001) of children. This does not mean that the nonclinical population cannot be further investigated in terms of vulnerability to anxiety disorders. Vallance and Garralda (2008) suggest that more than 25% of non-referred children report subclinical symptoms and over 20% have subclinical phobias.

Looking at the level of individual anxiety categories differentiation, we see that a more complicated picture emerges, especially when we consider the developmental version of anxiety disorders. A high degree of overlap characterizes subtypes of anxiety disorders (Kessler et al., 1994). In clinical child and adolescent samples, over 50% of children with one primary anxiety diag-

nostic also met the criteria for an additional anxiety disorder (Alessi & Magen, 1988; Strauss & Last, 1993). In community samples, comorbidity rates are much lower (Lewinsohn, Zinbarg, Seeley, Lewinsohn, & Sack, 1997; Valleni-Basile, Garrison, Jackson, Waller, McKeown, Addy, & Cuffe, 1994). Using *DSM-III* criteria, research has revealed limited evidence for the distinctiveness of overanxious disorder (but more substantial evidence for the newer GAD; Tracey et al., 1997) and more consistent results for social phobia, simple phobias, and SAD (Last et al., 1987; Strauss & Last, 1993). Insufficient attention has so far been paid to OCD and to PTSD (Schniering et al., 2000). If we look at prevalence rates of individual anxiety disorders in this age group, again results are controversial (see Cartwright-Hatton et al., 2006, for a review), with SAD as the dominant primary diagnosis (about 4%), and different—but generally lower—rates for OCD, GAD, and social anxiety, and somehow higher rates for simple phobias.

A final discriminant validity analysis targets the distinction between childhood anxiety disorders and other psychiatric constructs such as depression. Some theoretical accounts (e.g., Clark & Watson, 1991; King, Ollendick, & Gullone, 1991) have argued that the overlap in brain mechanisms and the high comorbidity rates among the two suggest that we are dealing with a common underlying factor (negative affect) and with other factors specific to each of the two (physiological arousal vs. anhedonia). Or, as Pennington (2002) frames it, “someone with an anxiety disorder has a lower threshold for an acute stress response, which then remits, while someone with a depressive disorder is stuck in a chronic stress response” (p. 126), both responses also presenting an adaptive value if adequately adapted to real-life circumstances (Nesse, 1999). Early in development, anxiety disorders are more common than depressive disorders (Cartwright-Hatton et al., 2006), leading some researchers to suggest the idea of a developmental continuum, where anxiety precedes depression (Kovacs, Gatsonis, Paulaskas, & Richards, 1989; Selligman & Ollendick, 1998). In studies with children and adolescents, comorbidity rates between anxiety and depression have been found to range from 16% to 62% (Brady & Kendall, 1992). This high comorbidity rate is partially intrinsic to the overlapping diagnostic criteria (irritability, restlessness, fatigue, concentration difficulties) but may also be a result of the masked manifestations of the disorders during early development, which leads to confusion and misdiagnosis.

Perhaps as a reflection of this last point, other differential diagnoses have been considered to be between childhood anxiety disorders (considered “internalizing”)

and behavior disorders (“externalizing”; Achenbach, 1985). Even if apparently opposite, these two types of disorders share some common features: interpretation of ambiguous information as threatening (Barrett, Rapee, Dadds, & Ryan, 1996; but see the difference at the level of response to threat) and diagnostic symptoms (restlessness, difficulties concentrating).

However, the value of a developmental approach does not reside in the recording of such static “snapshots” of manifestations and prevalence of anxiety disorders at different ages, but rather in a more realistic, dynamic view of their unfolding. At this point, some fundamental notions of a developmental psychopathology model (Cicchetti & Rogosh, 1996) have to be introduced, as they will also inform our multilevel analysis of vulnerability to anxiety. The notion of “equifinality” refers to the fact that similar outcomes can be reached from different initial states and through different pathways; “multifinality” reflects the fact that particular risk factors do not necessarily lead to the same outcome. A salient notion for anxiety research has been the idea of heterotypic continuity, or the notion that throughout development, the manifest form of psychopathology (and, most probably, the underlying circuitry as well) presents itself in various forms and leads to distinct outcomes. From this point of view, although pure etiological perspectives upon anxiety disorders are essential, they are not sufficient (Weems & Stickle, 2005), because different mechanisms can lead to distinct manifestations of anxiety disorders in children and adolescents, even if the initial risk factors are found to be similar.

Bearing this dynamic framework in mind, we can analyze the developmental stability and continuity of different childhood anxiety disorders. Two ideas that arose as a result of research in the field should be mentioned: anxiety disorders are extremely fluid across the life span, and early manifestations (or at-risk status in general) constrain but do not determine adult outcome, “raising questions about mechanisms that lead an underlying diathesis to be manifest or remain silent” (Pine, 2007, p. 632). Arguments for the second idea, concerning the lack of absolute deterministic power in the case of early anxiety disorders, result from studies revealing that a minority of at-risk individuals turn out to manifest adult disorders. Behavioral inhibition (Kagan, 1994) in toddlers predicts two- to fourfold increased risk for pediatric anxiety disorders (especially social phobia), but in terms of absolute risk, Pérez-Edgar and Fox (2005) show that no more than 50% of inhibited children develop pediatric anxiety disorders. In addition, about 50% of adolescents with anxiety disorder will develop adult psychopathology (Pine et al., 1998). The highest

remission rates are for separation anxiety disorder, and the lowest for panic disorder (less than 75%), as discussed by Vallance and Garralda (2008).

We will not present the results of longitudinal studies including treatment interventions here (but see below). However, they suggest that most children completely recovered, although a significant portion (about one-third) still received a different diagnosis at the 3-year follow-up (Cantwell & Baker, 1987). In other studies, whereas the diagnosis of 15% of children had shifted to a different anxiety disorder at the 3- to 4-year follow-up, the diagnosis of 13% changed to a depressive disorder, and 7% to an externalizing disorder, which supports the idea of fluidity of anxiety disorders across the life span (Last, Perrin, Hersen, & Kazdin, 1996).

Children with social phobia, SAD, or GAD show a two- to threefold greater risk for adult anxiety disorders (Pine et al., 1998; Gregory et al., 2007). Concerning outcome specificity, data generally provide stronger support for social phobia and SAD than for GAD. A study investigating the stability of anxiety diagnosis during a 6-month interval revealed that many of the initial diagnoses changed but actually were most likely to change to another anxiety disorder or to shift to subclinical levels of anxiety disorders, still revealing a greater vulnerability toward developing an anxiety disorder (Beidel, Flink, & Turner, 1996). On the other hand, an 8-year follow-up of adolescents age 9–18 provides evidence for the stability of the subtypes of anxiety disorders, especially in the case of social and simple phobias, but less so in the case of overanxious disorder (Cantwell & Baker, 1989). The lack of agreement regarding outcome specificity in these studies also diminishes the validity of delineating separate childhood anxiety disorders.

Regarding the predictive value of early anxiety disorders for the development of other types of psychopathology and general psychiatric problems, there is evidence for nonspecific outcomes derived from behavioral inhibition. It appears that toddlers high in behavioral inhibition face a greater risk for major depressive disorder (Caspi, Moffitt, Newman, & Silva, 1996); similarly, pediatric GAD also predicts risk for both adult anxiety and major depression (Pine et al., 1998; Gregory et al., 2007). Anxiety disorders in childhood lead to a two- to fivefold increase in anxiety disorders, depression, suicide attempts, and psychiatric admissions later in life and is associated with increased rates of substance abuse (Vallance & Garralda, 2008).

A final source of evidence for the developmental continuity of anxiety disorders is represented by family studies, which will be reviewed next. The general conclusion is that anxiety runs in families, presenting strong

cross-generational associations. In such cases, however, the developmental relationships might conceal the effects of genes, environment, and gene-environment interactions as possible causal mechanisms.

ETIOLOGY: GENETIC SUSCEPTIBILITY TO PEDIATRIC ANXIETY

In the pursuit of the etiological pathway to defining anxiety disorders, one essential question concerns the degree to which developmental continuities reflect the influence of genes or environment throughout the life span. While research on the genetics of anxiety in humans has primarily focused on adults (see above), in the late 1980s a series of studies appeared that made use of family and twin designs to investigate psychopathology earlier in development. An underlying aim was to find developmental shifts in genetic influences, which turned out to be a relatively common finding (e.g., Feigon, Waldman, Levy, & Hay, 2001; Topolski et al., 1997), with increasing age resulting in an increase in heritability (with a peak in early adolescence).

Comprehensive reviews of research into the genetics of childhood anxiety have been proposed (Eley, 1999; Gregory & Eley, 2007; Merikangas & Pine, 2002). Without aiming at a complete overview of this research, we have selected the main findings to help guide the clinician through recent findings regarding the genetic liability in the early development of anxiety disorders. From the beginning, it should be clear, however, that “to date, there remain no pathognomonic markers with which a presumptive diagnosis of an anxiety disorder may be made” (Merikangas & Pine, 2002, p. 867). The causes for such agnosticism include the difficulties of disentangling genetic from environmental contributions and their dynamic interplay throughout development, as well as the fact that many genes of small effect appear to be involved, rather than unique genetic causes. We will proceed with the review of main findings regarding familiarity, heritability, gene locations, and environmental influences on childhood anxiety and sketch out some future directions (endophenotypes, at-risk populations, comorbidity) that might help elucidate the remaining mysteries in the field.

Familiarity

Most studies have replicated the familial aggregation of all subtypes of anxiety disorders, with a three- to fivefold increased risk in the first-degree relatives of diagnosed probands (Merikangas & Pine, 2002). Moreover, this re-

lationship appears to be bidirectional, so that children's anxiety also increases the risk for such a disorder in their parents (Beidel & Turner, 1997). Childhood onset of anxiety disorder (before the age of 20) is also associated with a greater familial risk for anxiety symptoms in relatives (Goldstein, Wickramaratne, Horwath, & Weissman, 1997), probably due to a higher concentration of familial risk factors in the proband (Pennington, 2002). Unfortunately, this type of study is not sufficient for delineating genetic and environmental influences on the development of anxiety disorders.

Heritability

Adoption studies rarely focus on childhood anxiety, so they won't be presented at this point. Twin studies attempt to disentangle gene-environment influences by comparing data from monozygotic (MZ) and dizygotic (DZ) twins. They estimate the extent to which interindividual variation in anxiety symptoms is influenced by additive genetics (A; heritability), common or shared environmental influences (C), and non-shared environmental (E) influences. The results reveal a heritability rate between 30% and 40% (Kendler et al., 1992b, 1993), with distinct values for particular anxiety disorders, although the influence appears to be general and less disorder specific. The results in child samples reveal a 59% heritability rate for maternal reports of manifest anxiety (Thapar & McGuffin, 1995).

In terms of individual anxiety disorders, results from a large sample of child and adolescent twins (Topolski et al., 1997) suggest different heritability for overanxious disorder (37%, with non-significant C) and SAD (non-significantly heritable, but with a moderately significant $c^2 = 40$). A different result was obtained by Feigon et al. (2001), who evaluated SAD symptoms in the 3–18 years age band and found evidence for both genetic and shared environmental effects, with genetic effects increasing and C effects decreasing with age. The results of Eaves et al. (1997) bring nuance to the findings in terms of sex differences: while heritability for SAD was insignificant for boys, it was high for girls. Finally, Bolton et al. (2006) found high heritability for SAD (73%), with the remaining variance attributable to non-shared environment.

Heritability estimates for specific phobias are usually high (about 65%; Lichtenstein & Annas, 2000; about 80% and the remaining variance attributable to E in Bolton et al., 2006; a wider range of 16%–55%, depending on the type of phobia, in Lichtenstein & Annas, 1997). This suggests that fears and phobias in young children are more attributable to genetic than to environmental

influences. In the case of GAD (or previously overanxious disorder), results suggest additive genetic effects of about 37% (Topolski et al., 1997), or 32% among female twin pairs (Kendler et al., 1992a). Panic disorder also appears to be subject to genetic liability (Skre, Onstad, Torgersen, Lygren, & Kringlen, 1993; Kendler et al., 1995). Few controlled twin studies have targeted OCD, and there is weak evidence for heritability in the case of this disorder (Carey & Gottesman, 1981; Hudziak, Copeland, Stanger, & Wadsworth, 2004; Lenane, Swedo, Leonard, Pauls, Sceery, & Rapoport, 1990).

Some of the factors responsible for the inconsistencies in results are the manner in which questionnaires are completed (via mail or through direct interviewing; Pennington, 2002); the respondent (parental reports generally produce higher genetic estimates than children's self-reports; Eaves et al., 1997), the evaluation of anxiety as a personality trait, as a collection of symptoms, or as a clinical disorder (see Gregory & Eley, 2007, for an overview of differences); and the focus on state or TA (results in a youth sample of 10–18 years pointed to genetic and non-shared E influences on TA, and shared and non-shared environmental influences on state anxiety; Legrand, McGue, & Iacono, 2000).

Pennington (2002) reviews data that reveal a striking genetic correlation (essentially 1.0) between symptom measures of anxiety and depression (using child self-reports), suggesting a complete genetic overlap on these two measures. Eley and Stevenson (1999) pursued and refined the same comparison, deriving less correlated factors between anxiety and depression as outcome variables, but again, the genetic correlation was very high (the shared genetic factor accounted for 80% of the phenotypic correlation). The hypothesis put forward by Pennington (2002) for the clinical differentiation of these two disorders is the existence of non-shared environmental influences (e.g., loss for depression).

Molecular Genetics

Heritability studies generate hypotheses identifying specific candidate genes that may function as vulnerability markers for anxiety disorders. As reviewed above, most genetic association studies have focused on serotonin and dopamine genes. The few developmental studies conducted so far have shown mixed findings in children regarding 5-HTT, emphasizing the association either between the possession of two copies of the short 5-HTT allele and shyness in the third and fourth grades (Battaglia et al., 2005) or between the long version of the 5-HTT allele and shyness (Arbelle,

Benjamin, Golin, Kremer, Belmaker, & Ebstein, 2003), or revealing no association between this gene and anxiety/depression (Young, Smolen, Stallings, Corley, & Hewitt, 2003). For dopamine, there was evidence for a combined effect of the 7-repeat DRD4 allele and two copies of the short form in the promoter region of the serotonin transporter in infants' responses to anxiety-provoking situations (Lakatos et al., 2003). The functional polymorphism located in the promoter region of the 5-HTT gene has also been shown to moderate the effects of negative life events on depression symptoms in adolescents (Eley, Sugden, Gregory, Sterne, Plomin, & Craig, 2004).

Environment

In parallel with the need to specify candidate genes responsible for the heritability effects in the case of anxiety disorders, there is clearly a need to clarify the shared and non-shared environmental contributions to their development. One of the most relevant findings (and relatively unique compared to other disorders) supports the influence of shared environment on the development of anxiety disorders in children and adolescents. Shared family experiences during childhood thus appear to have a greater effect during childhood, an effect that diminishes in the later stages of life (Eley, 2001).

Environmental factors responsible for the early emergence of anxiety disorders might include acute and chronic stressors (e.g., maternal psychopathology; Armsden, McCauley, Greenberg, Burke, & Mitchell, 1990), modeling and some child-rearing practices (Krohne & Hock, 1991). Among the acute stressors, perinatal complications and prenatal exposure to substance use were not directly linked to the development of anxiety disorders, but rather to the development of behavior disorders (Allen, Lewinsohn, & Seeley, 1998; Merikangas, Avenevoli, Dierker, & Grillon, 1999). Stressful life events during adolescence were found to be predictive for both depressive and GAD symptoms (but only in females) in one of the few existing prospective studies (Pine et al., 2000). Exposure to early adverse experiences (separation or abuse) has been developmentally linked to posttraumatic stress disorder (Pynoos, Steinberg, & Piacentini, 1999).

However, in both clinical and community samples, the perception of environmental stress appears essential in mediating the stress-outcome relationship (Bernstein, Garfinkel, & Hoberman, 1989; Kashani & Orvaschel, 1990). Perceived lack of control (regarding access to food, water, and treats) induced in a quasi experiment

with young rhesus monkey led to an increase in fear and reduced exploratory behavior (Mineka, Gunnar, & Champoux, 1986).

Among the child-specific non-shared environmental influences, friendships and low school achievement appear to be related to anxiety (Goodyer, Wright, & Altham, 1989).

Future Directions

One relevant direction for future research to pursue is prospective investigations into very early anxiety manifestations in children at genetic risk of developing anxiety disorders. This information would provide an evaluation of premorbid risk factors and signal early markers of diagnostic value for this disorder. Merikangas and Pine (2002) review the existing studies revealing specificity of parent-child concordance within broad categories of anxiety disorders, as well as a lack of specificity with respect to depression. The next section will review some of the typical characteristics of early anxiety manifestation.

Another fruitful line of research suggested by Gregory and Eley (2007) is the investigation of comorbidity in twin studies in order to compare cross-twin cross-trait correlations in MZ and DZ twins. This would help elucidate the common or distinct genes that influence two possible outcomes (e.g., anxiety and depression) in such pairs. One example of such a study (Eley, Bolton, O'Connor, Perrin, Smith, & Plomin, 2003) conducted with 4-year-old twins found modest associations between five types of anxiety symptoms (general distress, separation anxiety, fears, obsessive-compulsive behaviors, and shyness). An important extension of these studies would be inspection of successive comorbidity, with different disorders occurring at different points of the ontogenetic trajectory (e.g., Gregory, Eley, & Plomin, 2004; Silberg & Bulik, 2005; Silberg, Rutter, Neale, & Eaves, 2001).

Finally, as suggested previously by research with adult participants, it might be more relevant to focus on identifying endophenotypes, which are more proximal to genes activity and related to neurophysiological, biochemical, endocrinological, cognitive, or neuroanatomical characteristics of functioning in children with anxiety disorders (Gregory & Eley, 2007). The following section will attempt to reveal potential markers of such endophenotypes at multiple levels, which, in turn, might represent stronger criteria for identifying and treating anxiety disorders than current symptoms classifications.

OTHER INTRINSIC VULNERABILITY MARKERS

At this point in our analysis we will briefly present the intrinsic factors (ranging from the broad level of temperamental or personality predispositions to very specific psychophysiological and neurochemical responses) that have been shown to represent early signs of vulnerability to the development of anxiety disorders. Table 13.2 provides a synopsis of these markers, following the classification offered by Merikangas and Pine (2002). As the neural circuitry underlying threat-related behaviors can be considered an integral part of an information-processing approach, brain markers of childhood anxiety will be reviewed at greater detail in the next section.

First, a general predisposition toward anxiety disorders can be seen in specific temperamental or personality features such as behavioral inhibition, generally negative affectivity (although this is also a nonspecific predictor of psychopathology in general), low effortful control. We refer the reader to comprehensive reviews regarding temperament-anxiety relations by Clark (2005), Lonigan and Phillips (2001), Muris and Ollendick (2005), Tıncaş, Benga, and Fox (2006). However, the exact nature of this relationship is not clear, since temperament could play (1) a causal role, representing a predisposition to anxiety (especially amplifying the echo of a relevant stressor to trigger the onset of a disorder); (2) a moderator role, modulating the expression of the disorder or directly shaping the environment of the child; or (3) the role of a dependent variable, itself altered by anxiety (Lonigan & Phillips, 2001).

Anxiety sensitivity (AS) is a controversial construct that refers to the "degree of displeasure" produced by the experience or the anticipation of anxiety. While some authors question the distinctiveness of this trait-like factor from TA or general fear (Lilienfeld, Turner, & Jacob, 1998), others argue that it is a qualitatively distinct phenomenon, both theoretically and empirically (McNally, 1996; Reiss, 1997). Without taking sides in this debate, we must note that AS was proved to be a specific predictor of anxiety disorders (but not of depression) in nonclinical samples (Hayward, Killen, Kraemer, & Taylor, 2000; Pollock, Carter, Dierker, Chazan-Cohen, & Merikangas, 2002; Schmidt, Lerew, & Jackson, 1997; Weems, Hammond-Laurence, Silverman, & Ginsburg, 1998). This specificity, together with the proof of genetic control of AS (Eley, Gregory, Clark, & Ehlers, 2007; Stein, Jang, & Livesley, 1999), suggests

13.2

Intrinsic Vulnerability Markers Associated With Childhood Anxiety

DOMAIN	MARKER	CONCLUSIONS	DEVELOPMENTAL STUDIES
Temperament/ personality	Behavioral inhibition	There are specific associations between childhood inhibition and later anxiety disorders. Children of parents with anxiety disorders show increased behavioral inhibition. Maternal ratings of shyness in late childhood are associated with anxiety disorders in adolescence.	Biederman et al., 1990, 1993; Hirshfeld et al., 1992; Beidel & Turner, 1997; Rosenbaum et al., 1991; Prior et al., 2000; Lonigan et al., 1994; Joiner et al., 1996; Lonigan et al., 1999; Tıncaş et al., 2007; Muris & Ollendick, 2005; Caspi et al., 1995; Schmidt et al., 1997; Pollock et al., 2002; Hayward et al., 2000
	Negative affectivity/ neuroticism	General risk for psychopathology, including anxiety and depression <i>or</i> specific concurrent or predictive associations with anxiety symptoms/ disorders.	
	Low effortful control	In combination with high neuroticism, low effortful control can predispose the individual to internalizing disorders.	
	Lack of control, inhibition, sluggishness	At age 5, lack of control and inhibition were predictors of anxiety in boys, and lack of control and sluggishness in girls.	
	Anxiety, sensitivity	Anxiety and sensitivity are specific predictors of anxiety disorders (especially panic attacks).	
Autonomic reactivity and psychophysiologic responses	Heart rate Heart period variability	Under conditions of novelty/stress, children with behavioral inhibition or anxiety disorders exhibit a shift from parasympathetic to sympathetic control (increase in heart rate, reduction in high frequency components of heart period variability). Enhanced cardiovascular activity following an accident predicted PTSD.	Kagan, 1995; Rogeness et al., 1990; Shalev et al., 1998; Merikangas et al., 1999; Grillon et al., 1997; Kagan, 1995
	Skin conductance	Fearlessness (modeled by skin conductance) is associated with low anxiety and behavior problems.	
	Startle reflex abnormalities	Startle reflex abnormalities have been found in children of adults with anxiety or in inhibited children at risk for anxiety disorders.	

(continued)

13.2

Intrinsic Vulnerability Markers Associated With Childhood Anxiety (*continued*)

DOMAIN	MARKER	CONCLUSIONS	DEVELOPMENTAL STUDIES
Ventilatory function	Sensitivity to respiratory perturbation	Increased CO ₂ sensitivity in children with anxiety disorders. Abnormalities in respiration as revealed by smoking in adolescents predispose to later anxiety.	Pine et al., 2000; Breslau & Klein, 1999; Johnson et al., 2000
Neurochemical and Neurohormonal	Salivary cortisol (index of greater responsivity of the HPA axis)	When compared to extremely uninhibited children, extremely anxious preschoolers have higher morning cortisol levels. In children attending full-day day care, shyness and sadness were positively correlated with cortisol elevations from morning to afternoon.	Schmidt et al., 1997; Kagan et al., 1987; Dettling et al., 1999; Tout et al., 1998; Sallee et al., 2000
	Noradrenergic system	Manipulations of the noradrenergic system have been shown to selectively elevate anxiety symptoms in children with anxiety disorders.	

that AS might represent a “potential endophenotype for childhood panic/somatic symptoms in molecular genetic research” (Gregory & Eley, 2007, p. 208).

Second, anxiety symptoms/disorders in children and adolescents have also been associated with a specificity of autonomic responses to threatening stimuli (heart rate, heart period variability, blood pressure, and catecholamine levels), psychophysiological reactions (skin conductance, pupil dilatation, startle reflex), and particular aspects in the ventilatory function (sensitivity to respiratory stimulation via inhaled CO₂ or lactate infusion). Some of these perturbations appear to be specific to certain (especially acute) emotional states, but the direction of the influence (anticipatory or as a downstream manifestation of anxiety states) remains uncertain (Merikangas & Pine, 2002).

Finally, specific neurochemical alterations have been found to be predictive or associated with anxiety disorders. While manipulations of the serotonergic system or the noradrenergic system have mostly been conducted in animal models or in the case of adult participants (see Sallee et al., 2000, for an exception), some

studies with children have demonstrated the alterations in the hypothalamic-pituitary-adrenal (HPA) axis regulation, as revealed by elevated cortisol levels in the case of anxiety disorders.

AN INFORMATION-PROCESSING APPROACH TO CHILDHOOD ANXIETY

So far, we have reviewed the early vulnerability markers of anxiety disorders with little clarification of their involvement in the generation or maintenance of these disorders. The genetic, temperamental, or psychophysiological predispositions should be related to the neural circuitry underlying anxious behavior and, ultimately, to the cognitive functioning of a child with anxiety. Information-processing frameworks focus on the cognitive biases and distortions characteristic of childhood anxiety and attempt to model the sequence of steps involved in the generation, maintenance, and modification of information through the cognitive system (see Alfano, Beidel, & Turner, 2002; Daleiden & Vasey, 1997; Pine,

2007; Vasey & MacLeod, 2001). Only recently have such frameworks attempted to integrate findings from neuroscience that are of direct relevance to the processes involved in anxious thoughts and behaviors (e.g., Pine, 2007; Telzer, Mogg, Bradley, Mai, Ernst, Pine, & Monk, 2008).

In the information-processing framework outlined by Pine (2007), he explicitly argues that it is difficult to provide matches between clinical criteria for a disorder and constructs from neuroscience. Neural function has been related to ongoing information-processing operations, rather than to static clinical criteria. He proposes an alternative view, which we describe here, as it forms the basis for our review of neurocognitive functioning in childhood anxiety. Genetic and environmental influences shape the underlying neural circuitry (Factor 1), which itself does not map directly onto anxiety phenotypes but rather affects the way information is being processed (Factor 2). This information processing translates into anxiety disorders, anxiety dimensions (state-trait, subclinical features, neuroticism), or temperamental predispositions (high reactivity, behavioral inhibition; Factor 3). We have so far discussed the genetic and environmental influences acting upon Factor 1, and their distal outcome (Factor 3); it is now time to analyze the pathways between specific neuroscience findings and cognitive functioning in children with anxiety. We will follow the same tripartite focus upon groups of cognitive processes relevant to pediatric anxiety as that used in Pine's the framework and will refer to (1) threat-attention capture, (2) threat appraisal, and (3) memory and learning. This type of study emerged in the late 1990s, with an initial focus on the controversial results of attempts to replicate the attentional and inferential biases found in adults among children and adolescents, and has progressed through a refinement of tasks and the search for neural correlates of these processes.

Attention to Threat

In adults, it is a generally accepted (and widely documented) fact that stimuli corresponding to specific threat-related concerns of the anxious individual consume increased attentional resources (see Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van IJzendoorn, 2007, for a recent comprehensive meta-analysis). This has been proved especially regarding (1) the orienting component of attention, through use of the Posner-orienting or the dot-probe paradigm, and (2) attention orienting and regulation, through use of the emotional Stroop. De-

velopmental research has generally followed the same tracks, but the results have been conflictual in revealing a bias toward or away from threatening stimuli; moreover, some studies have failed to show any anxiety-specific bias regarding these stimuli.

Simple detection of threatening faces was proved to be faster in typical children 7–10 years of age (Hawwin, Donnelly, French, Richards, Watts, & Daley, 2003). Studies using modified versions of the Stroop task to include threat-related verbal or pictorial stimuli have found either longer latencies on these stimuli in anxious children (Martin, Horder, & Jones, 1992; Martin & Jones, 1995—for children 4–13 years old in both studies) or a nonspecific effect of concern-related stimuli, irrespective of anxiety group (Kindt, Brosschot, & Everaerd, 1997; Mogg, Mathews, Bird, & MacGregor-Morris, 1990). Analyzing the reasons for these inconsistencies, Vasey and MacLeod (2001) conclude, "The modified Stroop task has proven to be an unreliable method of demonstrating attentional bias to feared stimuli in children suffering from specific fears" (p. 261). This lack of an effect was found in relation to not only the outcome of anxiety disorders, but also the temperamental dimension of anxiety. Schwartz, Snidman, and Kagan (1996) and Kagan, Snidman, Zentner, and Peterson (1999) found no slowing in inhibited children (or children who had been inhibited as toddlers) related to the threat words. An interesting finding was the strong effect of trauma-related words in children suffering from PTSD, and even in children who had a parent suffering from PTSD (Moradi, Taghavi, Neshat Doost, Yule, & Dalgleish, 1999).

Studies using probe detection tasks have subjects identify the targets in certain target spatial positions that replace threat-related stimuli; the capture of attention is measured by the latency to identify these targets. This type of study has been much more consistent in confirming the presence of an anxiety-linked effect in anxious children and youths. Some have shown an attentional bias toward the threatening stimuli in clinical and nonclinical populations of children as a function of TA (Heim-Dreger, Kohlmann, Eschenbeck, & Burkhardt, 2006; Schippell, Vasey, Cravens-Brown, & Bretveld, 2003; Telzer et al., 2008; Vasey, Daleiden, Williams, & Brown, 1995—only in older children), but not of state anxiety (Vasey, El-Hag, & Daleiden, 1996). Neuroimaging results (e.g., Telzer et al., 2008) revealed an association between TA and the right dorsolateral prefrontal cortex (PFC) on the contrast of trials reflecting attentional bias toward angry faces, and between TA and right ventrolateral PFC on all trials with face stimuli, irrespective of emotional content. Monk et al. (2006)

also used a visual probe task in adolescents with GAD and revealed an attention bias away from angry faces, correlating with an enhanced activation of the right ventrolateral PFC in response to the angry facial expressions. The specific activation of lateral PFC areas only in the case of TA, areas associated with increased cognitive control, may suggest an association between TA and greater processing needs in performance of the task and reflects the interplay between threat detection and threat appraisal, an issue that will be further stressed throughout this section.

Regarding developmental trends, studies have generally failed to reveal anxiety-linked attentional biases in children younger than 7–12 years of age (Vasey & MacLeod, 2001); prior to that age, studies reveal a non-anxiety-specific bias toward threatening stimuli in all children (Vaish, Grossman, & Woodward, 2008). An interesting related finding is the fact that healthy adolescents have an orienting bias toward threat where healthy adults show no such preference, and anxious adolescents display avoidance where anxious adults display vigilance (Monk et al., 2006). Pine (2007) considers this to be a proof of a maturational increase in the threshold for threats affecting attention orienting. The developmental question is most relevant: how and when does the association between anxiety and selective attention become specialized? The search for the earliest predictors of childhood anxiety might benefit from further refinement of methodological tools that might not confound, for instance, the targeted effect of stimuli valence with overall inhibitory demands (such as the ones from the Stroop task, which might be too difficult altogether for very young children).

The neural bases for the attention biases include the amygdala, which plays a role in the detection of and response to threat-related cues and the PFC in modulating this attention bias (Bishop, 2007; Monk et al., 2006). Studies investigating amygdala dysfunction in pediatric anxiety have revealed both structural modifications (increased size, see de Bellis et al., 2000; decreased size, see Millham, Nugent, Drevets, Leibenluft, Ernst, Charney, & Pine, 2005) and functional hyperactivation (in the case of fearful faces, see Thomas et al., 2001; in previously inhibited children, see Schwartz, Wright, Shin, Kagan, & Rauch, 2003).

Threat Appraisal

An interpretative bias that appears in later explicit stages of stimulus classification has been more consistently documented in children. After the initial automatic classification of stimuli, a more elaborated

iterative appraisal process assigns meaning to the stimulus according to the individual's goals. A correlation between level of TA and the interpretation of ambiguous stimuli as threatening has been found by several studies using pictorial stimuli (in children 7–9 years old by Hadwin, Frost, French, & Richards, 1997; in children and adolescents 9–16-years old by Taghavi, Moradi, Neshat-Doost, Yule, & Dalgleish, 1999) and vignettes and stories (Barrett et al., 1996; Bell-Dolan, 1995; Bogels & Zigterman, 2000; Chorpita, Albano, & Barlow, 1996; Muris, Kindt, Bögels, Merckelbach, Gadet, & Moulaert, 2000). Beyond these biased interpretations relative to controls, children with anxiety have also been shown to present more negative anticipations of future events (Magnusdottir & Smari, 1999; Spence, Donova, & Brechman-Toussaint, 1999). Interestingly, this is indirectly reflected by their maladaptive, usually avoidant coping styles (Barrett et al., 1996; Chorpita et al., 1996; Bell-Dolan, 1995; Vasey, Daleiden, & Williams, 1992). Not only verbal reports but also some defensive reflexes (autonomic, electromyographic, respiratory, and oculomotor) could be used in inferring threat appraisal in children and youths (e.g., Pine, Klein, Roberson-Nay, Mannuzza, Moulton, Woldehawariat, & Guardino, 2005).

Regarding the disorder specificity of these appraisal biases, dissociation was found in the responses to specific stimuli in the case of SAD and social phobia. While SAD-diagnosed adolescents manifest appraisal biases for respiratory threats, youths with social phobia are biased in their appraisal of social threats, and not vice versa (Pine et al., 2005).

There are certain developmental trends in the processes of threat appraisal, especially regarding the hierarchy of elements: while children classify specific objects as threatening, adolescents tend to classify broader classes of stimuli (e.g., all public speech contexts) as menacing. This is probably the result of their cognitive and linguistic development, which allows for more elaborated scenarios and complex classifications of threats and of threat-related responses. This change is backed up by modifications in the neural circuitry related to threat appraisal, comprising the ventral PFC and the posterior temporal cortex, which play a role in the evaluation of stimulus salience (Pine, 2007). Monk et al. (2006) found enhanced activity in ventrolateral PFC when young participants were performing a threat dot-probe task. McClure et al. (2007) found that adolescents with GAD presented a facilitation of amygdala activation, combined with ventral and medial PFC engagement, when making threat appraisals for facial expressions.

Memory and Learning

The cognitive distortions at the memory and learning level have been investigated far less in children, partially as a consequence of the inconsistent results obtained from the investigation of emotional memory biases in adults (Mathews, Mackintosh, & Fulcher, 1997; Miu et al., 2005). However, a review of short-term and working memory functioning in anxious children (Visu-Petra, Ciairano, & Miclea, 2006) found proof for the detrimental effect of anxiety upon verbal memory (especially in conditions with high load) in tasks involving emotionally neutral stimuli. At the basic level of short-term memory, the microanalysis of preschoolers' responses in verbal memory span tasks (Visu-Petra, Miclea, Cheie, & Benga, 2008) revealed the predictive effect of nonclinical TA, which was marginal for performance accuracy (number of recalled items) and more consistent for performance efficiency (longer durations of preparatory intervals and of inter-word pauses). The results were interpreted in the framework of the attentional control theory (M. W. Eysenck et al., 2007), suggesting that anxiety primarily affects processing efficiency. Only if anxious subjects cannot compensate by investing supplementary time/resources involved (e.g., conditions of high load) will a detrimental effect of anxiety upon accuracy be visible. In the same conceptual framework, Owens, Stevenson, Norgate, and Hadwin (2008) found that verbal working memory performance significantly mediated the relationship between TA and academic performance in adolescent's age 11–12 years. When clinical child samples were investigated, verbal and visual memory deficits predicted future anxiety disorders (Pine et al., 1999), correlated with the presence of SAD and overanxious disorder (Toren et al., 2000), and were specific to major depressive disorder, but not social phobia and GAD (Gunther, Holtkamp, Jolles, Herpertz-Dahlmann, & Konrad, 2004). Finally, Vasa et al. (2007) showed that children and adolescents with social phobia had reduced visual but not verbal memory scores.

Data regarding emotional memory in childhood anxiety have been inconsistent or negative (Vasa et al., 2007). Using word lists, Daleiden (1998) found evidence of a memory bias favoring negative verbal information (only conceptual, not perceptual) in trait anxious eighth-grade children. He interprets the results as proof of the deficit in using attentional disengagement as an emotional regulatory skill in children with high levels of anxiety. Visu-Petra, Țincaș, Cheie, and Benga (in press) found that preschoolers with high trait anxiety are slower in a memory updating task, and are differentially influenced by the emotional valence of the facial expressions than

their low-anxious counterparts. More specific, they were slower and less accurate in detecting and remembering happy faces, and more accurate in response to angry faces. In a clinical sample, Pine, Lissek, Klein, Mannuzza, Moulton, Guardino, and Woldehawariat (2004) used a face memory paradigm and found that anxiety disorders did not predict memory performance. Ladouceur, Dahl, Williamson, Birmaher, Ryan, and Casey (2005) used an emotional *n*-back task in a mixed clinical sample; no significant interference of negative pictures was found on the memory performance of the anxiety group.

Regarding the neurobiological underpinnings of the anxiety-memory relationship, studies with adult participants have suggested that non-emotional memory deficits might reflect dysfunctions in the medial temporal lobe, a region that is implicated in both anxiety and memory (Charney, 2003; Vasa et al., 2007). A second hypothesis relates to the secondary nature of the memory dysfunctions, which emerge as a consequence of biased attentional processes.

There is an unfortunate research tradition of studying these three types of anxiety-related cognitive biases separately. However, their confluence is obvious, because (1) appraisal is influenced by early automatic attentional capture and (2) both orienting and appraisal contribute to the encoding and subsequent processing of stimuli within memory systems. Empirically, there has been little explicit proof of this relationship in the case of childhood anxiety. Pine et al. (2005) have documented significant correlations between the time required for explicit threat appraisal and ratings of threat intensity. They suggest that appraisal biases may in fact emerge during development through interactions with attention, as children with automatic biases in stimulus detection might be expected to learn to classify stimuli as dangerous. An interesting research avenue would be investigating how learning might alter the attention-orienting and appraisal biases (Pine, 2007).

CLINICAL IMPLICATIONS: ASSESSMENT AND TREATMENT OF CHILDHOOD ANXIETY

The assessment process in childhood anxiety has mostly conformed to a clinical symptoms-based approach. However, as revealed throughout this chapter, in the past decades more and more studies have attempted to reveal the neurobiological and cognitive correlates that might help create a more comprehensive profile of these disorders. For very young ages, mostly symptoms

checklists with different informants (parents, teachers) have been used. In older children, structured diagnostic interviews and self-report measures are the preferential tools, which make use of the child as the best informant regarding his or her inner states and behaviors (see Schniering et al., 2000, for a review of instruments, with their advantages and problems). These instruments have either emphasized broad distinctions, such as the one between emotional (internalizing) and behavioral (externalizing) syndromes (Egger & Angold, 2006), or focused specifically on characterizing particular anxiety subtypes (e.g., Spence, Rapee, McDonald, & Ingram, 2001). We can refer the clinician to the comprehensive *Handbook of Infant, Toddler, and Preschool Mental Health Assessment* (DelCarmen-Wiggins & Carter, 2004) for a collection of instruments designed to assess anxiety disorders in early development.

A common underlying question that has been emphasized throughout this chapter relates to the clinical value of these vulnerability factors. Do they represent a specific underlying risk—and thus a potential target for anxiety prevention? Or are they simply overt expressions of anxiety disorders? Although we would be tempted to choose the first answer, there is some inconsistent evidence regarding their trait-like nature: threat-related biases appear amenable to change after therapy (e.g., orienting biases, Williams et al., 1996) or even after brief training exercises (MacLeod et al., 2002; Monk et al., 2004). Children's threat interpretations after intervention involving CBT plus parental involvement revealed significant decreases (Barrett et al., 1996). Interestingly, this was not the case in the CBT-only intervention; this reveals the role of the parental environment in the maintenance of specific cognitive styles in anxious children (Alfano et al., 2002). Cognitive symptoms (negative cognitions and phobias) also decreased as a result of child and parent interventions for phobic children (Silverman, Kurtines, Ginsburg, Weems, Lumpkin, & Carmichael, 1999; Spence, Donovan, & Brechman-Toussaint, 2000). However, there appears to be a lack of specificity regarding the cognitive targets of the CBT interventions and the change mechanisms that they produce, with some studies producing the desired changes only through the use of behavioral, not cognitive, intervention (Beidel, Turner, & Morris, 1995).

Cognition has been examined as a causal factor in the development of anxiety in children (e.g., Kendall & Ronan, 1990) or as a moderator between specific vulnerabilities and anxiety (e.g., Chorpita & Barlow, 1998). As a possible mechanism for the transformation of an at-risk but unaffected individual to an individual with an anxiety disorder, Pine (2007) suggests “the devel-

opment of heightened arousal for threats, emerging against a background of mild hypersensitivity to diverse threats” (p. 637). Intervention strategies (either externally mediated or discovered by at-risk children themselves) would target a more accurate differentiation between real and potential threats, although the hypersensitivity toward threat might remain constant throughout development. Departing from the traditional symptoms-based treatment (see Chorpita & Southam-Gerow, 2006, for a recent review of childhood anxiety treatments and outcomes), Daleiden and Vasey (1997) used the information-processing framework to suggest specific interventions targeting distinct stages of information processing. The strategies would aim to change early encoding by broadening the information that children attend to; correct interpretation biases and distortions; change anxious children's goals; or enhance response generation, selection, and enactment. These information-processing strategies would provide a complementary approach to the classical CBT treatment, increasing both the theoretical specificity of the intervention and the empirical validity of the outcomes.

Another developmental issue is the heterotypic continuity of the underlying vulnerability factors and of anxiety disorders themselves. Indeed, the review of vulnerability markers, especially in the information-processing framework, has revealed that nonclinical TA and clinical anxiety disorders present many similarities, supporting the view of an anxiety continuum. Moreover, anxiety itself often translates into other forms of psychopathology during development (especially anticipating depression), suggesting a larger psychopathology continuum. Any analysis of these metamorphoses should take into account the development of cognitive and regulatory processes involved in anxiety. The lack of a consistent and identifiable anxiety-related effect upon cognition prior to 7 years of age might only be a result of children's lack of the cognitive skills to report cognitive contents or to comply with task demands (Alfano et al., 2002), or a reflection of specific early deficits in emotion understanding among anxious children (Southam-Gerow & Kendall, 2000). Self-appraisal and self-descriptions are also more related to physical standards before the age of 8 (Vasey, 1993), as younger children have difficulties in social comparisons.

As Pine (2007) suggests, clinicians hoped that by extracting specific clusters of symptoms that resulted in categorical definitions of anxiety, they could “carve nature at its joints, identifying syndromes closely linked to brain dysfunction” (p. 632). However, the multiple types of evidence brought together in this chapter

(prevalence and comorbidity, genetic, developmental, from cognitive psychology and neuroscience) lead to questions about the specificity and differentiation of the clinical syndromes, suggesting the need for an alternative classification closer to brain function and dysfunction (i.e., endophenotypes).

Post-Traumatic Stress Disorder

Gina Manguno-Mire
C. Laurel Franklin

Post-Traumatic stress disorder is an anxiety disorder that develops in response to a traumatic event or stressor and is characterized by symptoms of reexperiencing, avoidance, and hyperarousal. PTSD is rather unique in that it is one of two psychiatric disorders in the fourth edition text revision of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR*; American Psychiatric Association, 2000) that is tied directly to a specified life event. This feature of PTSD has significant implications for the diagnosis, etiology, and treatment of the disorder, as well as psychosocial factors, including its development in a medicolegal context.

INTRODUCTION

Although PTSD became a diagnostic category relatively recently, the symptoms of PTSD have been observed for centuries. Historical depictions of PTSD can be found in the story of Ulysses in Homer's classic works, the *Iliad* and *Odyssey*, which make numerous references to the devastating impact of the Trojan War among those who survived (Shay, 1994). The damaging effects of combat and the long-term psychological consequences among soldiers were described for years prior to the coining of the term "post-traumatic stress disorder" in 1980. The terms "soldier's heart," "shell shock," "combat fatigue," "gross stress reaction," "war neurosis," and

"combat neurosis" have all been used to describe what we now recognize as war-related PTSD.

Combat-related trauma is not the only type of trauma that has been linked to the development of long-term negative psychological sequelae. In fact, decades before the introduction of contemporary diagnostic nomenclature, Kraepelin (1896) coined the term "fright neurosis" (*Schreckneurose*) to denote anxiety symptoms that developed after serious accidents and physical injuries (Jablensky, 1985). Similarly, Oppenheim (1892) referred to "traumatic neurosis" in an attempt to describe anxiety in response to extreme stress (Kraepelin, 1896). Following the Great Fire of London in 1666, a famous diarist of the 17th century, Samuel Pepys, wrote: "It is strange to think that to this very day I cannot sleep a night without great terrors of fire" (qtd. in Daly, 1983, p. 66). It is clear that the symptoms of PTSD have been observed throughout history, long before the modern concept of post-traumatic stress disorder was developed.

PTSD can develop following a wide range of traumatic life events. Examples include war, rape, torture, criminal assault, interpersonal violence, childhood trauma, accidents, physical injury, the sudden death of a loved one, exposure to natural or man-made disasters, and physical illness/medical procedures. Traumatic events can be directly experienced by the individual or can be learned of secondarily; for example, one might be confronted with information about a traumatic event

occurring to a close friend or relative (American Psychiatric Association, 2000). Researchers (e.g., McNally, 2003a) have commented that learning about an event happening to someone else “seems qualitatively different” (p. 231) from firsthand experience with a trauma. Secondary trauma exposure as a diagnostic criterion remains controversial and may account for some of the methodological inconsistencies among studies, particularly in the area of psychobiological research (Duke & Vasterling, 2005).

In terms of risk for developing PTSD, researchers have examined a number of different types of variables and categorize them as follows: (1) pre-trauma variables, such as personal characteristics (e.g., sex, age, educational level, premorbid psychiatric history, and personality); (2) trauma variables (e.g., type of trauma, trauma severity); and (3) post-traumatic variables (e.g., coping, social support, life stress) (Duke & Vasterling, 2005). A thorough discussion of all these factors is beyond the scope of this chapter; however, the interested reader is referred to the comprehensive text by Friedman, Keane, and Resick (2007) for further detail.

In general, researchers have demonstrated that the severity, duration, and proximity of an individual's exposure to a traumatic event are the most important factors affecting his or her likelihood of developing PTSD, and that peri- and post-traumatic variables (as opposed to pre-traumatic factors) are the strongest predictors of PTSD (see meta-analysis by Ozer, Best, Lipsey, & Weiss, 2003). However, research evidence indicates that psychosocial variables, such as interpersonal (social) support, demographic factors (e.g., age, family history, IQ), and intra-individual factors (e.g., trauma history, childhood variables, premorbid mental disorders, personality factors) influence an individual's predisposition to developing PTSD. Women and young adults as well as combat veterans are at greater conditional risk for the development of PTSD than nonveteran men and older adults (see Friedman et al., 2007).

Although the emotional and intrapsychic experiences of PTSD are substantial, PTSD takes a considerable physical, interpersonal, and psychosocial toll on individuals with the disorder. Individuals with PTSD are more likely to use more costly and specialized medical services; to suffer negative financial consequences and reductions in earning potential; to experience relationship distress and have higher rates of separation, divorce, and family problems; experience employment difficulties; and reductions in quality of life (Keane & Barlow, 2002; Koss, Koss, & Woodruff, 1991; Kulka et al., 1990). Therefore, the myriad of associated problems and secondary consequences of traumatic stress are

considerable and, in many cases, as debilitating as the core symptoms of PTSD.

SYMPTOMS

PTSD symptoms are classified according to the currently accepted diagnostic nomenclature in the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 2000), presented in Table 14.1. The historical evolution of symptomatic criteria is worth noting. In the first edition of the *DSM* (American Psychiatric Association, 1952), there were no explicit diagnostic criteria for PTSD, although the term “gross stress reaction” was used to describe individuals who had previously been relatively normal but developed symptoms following exposure to extreme stress. Surprisingly, with the publication of the *DSM-II* in 1968, this category was eliminated. Theories about the potential political and social influences that influenced this development and its subsequent about-face in the third edition abound (see Shalev, Yehuda, & McFarlane, 2000). When the *DSM* was revised in 1980, PTSD was included for the first time as an official diagnosis, although the precipitating event was considered to be an extreme life stressor outside the range of normal human experience (American Psychiatric Association, 1980). With the publication of the *DSM-IV* in 1994 and the slightly revised edition issued in 2000 (American Psychiatric Association, 1994, 2000), several changes were introduced, along with the introduction of a new associated disorder: acute stress disorder. Of note, in the *DSM-IV* Criterion A was broken into two parts: A1 and A2. Criterion A2 (i.e., “the person's response involved intense fear, helplessness, or horror”) is significant because an understanding of the individual's emotional response at the time of the traumatic event is a prerequisite for determining a diagnosis.

Since the publication of *DSM-III*, epidemiological research has demonstrated that traumatic events are actually fairly common (Duke & Vasterling, 2005). For a detailed description of the epidemiology of traumatic life events and prevalence estimates in the general population, please refer to more comprehensive reviews by Breslau (2001, 2002); Fairbank, Ebert, and Costello (2002); and Hidalgo and Davidson (2000). Traumatic events are no longer necessarily considered outside the range of normal human experience. Therefore, according to the current diagnostic nomenclature (American Psychiatric Association, 2000), a diagnosis of PTSD can be considered as long as the traumatic event and the person's immediate emotional reaction to it meet standardized criteria (see Table 14.1).

14.1

DSM-IV-TR Criteria for PTSD

CRITERION A (TRAUMATIC STRESSOR)

The person has been exposed to a traumatic event in which both of the following occurred:

- (1) The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of him- or herself or others.
- (2) The person's response involved intense fear, helplessness, or horror. In children, this may be expressed instead by disorganized or agitated behavior.

CRITERION B (INTRUSIVE RECOLLECTION)

The traumatic event is persistently reexperienced in one (or more) of the following ways:

- (1) Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. In young children, repetitive play in which themes or aspects of the trauma are expressed may occur.
- (2) Recurrent distressing dreams of the event. In children, there may be frightening dreams without recognizable content.
- (3) The person acts or feels as if the traumatic event were recurring (involves a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur upon awakening or when intoxicated). In young children, trauma-specific reenactment may occur.
- (4) Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
- (5) Physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.

CRITERION C (AVOIDANCE)

Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by 3 (or more) of the following:

- (1) Efforts to avoid thoughts, feelings, or conversations associated with the trauma
- (2) Efforts to avoid activities, places, or people that arouse recollections of the trauma
- (3) Inability to recall an important aspect of the trauma
- (4) Markedly diminished interest or participation in significant activities
- (5) Feeling of detachment or estrangement from others
- (6) Restricted range of affect (e.g., unable to have loving feelings)
- (7) Sense of foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)

(continued)

14.1

DSM-IV-TR Criteria for PTSD (*continued*)**CRITERION D (HYPERAROUSAL)**

Persistent symptoms of increased arousal (not present before the trauma), as indicated by 2 (or more) of the following:

- (1) Difficulty falling or staying asleep
- (2) Irritability or outbursts of anger
- (3) Difficulty concentrating
- (4) Hypervigilance
- (5) Exaggerated startle response

CRITERION E (DURATION)

Duration of the disturbance (symptoms in Criteria B, C, and D) is more than one month.

CRITERION F (FUNCTIONAL IMPAIRMENT)

The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:

- Acute: if duration of symptoms is less than 3 months
- Chronic: if duration of symptoms is 3 months or more
- Delayed Onset: if onset of symptoms is at least 6 months after the stressor

The key features that distinguish PTSD from other psychological disorders are the reliving/reexperiencing symptoms (nightmares, flashbacks, intrusive memories), avoidance of trauma reminders, and anxious arousal (insomnia, irritability, diminished concentration, hypervigilance, startle response). Individuals with PTSD relive the traumatic event in a number of ways. The individual experiences recurrent intrusive recollections of the traumatic event in the form of persistent thoughts or memories, has nightmares, and may experience flashback episodes in which he or she experiences the traumatic event in a vivid manner, almost as though the event is happening all over again. Often flashbacks involve input from all of the senses and are extremely frightening. Exposure to reminders of the

trauma produces intense psychological reactivity and emotional distress. Avoidance symptoms involve avoiding reminders of the trauma or enduring them with considerable distress. Traumatic reminders or cues are particular stimuli associated with the traumatic event, such as locations, times, events, conversations, activities, or people. Individuals may also have difficulty remembering important aspects of the traumatic event and lose interest in routine or pleasurable activities. Other avoidance symptoms are the sense of a foreshortened future, feelings of detachment or estrangement from others, and emotional numbing, which is an inability to feel positive emotions, such as love, contentment, or happiness. Hyperarousal is often the most distressing symptom and is frequently the one reported

to health care professionals. This includes symptoms of insomnia or difficulty sleeping, irritability or strong feelings of anger, attention and concentration difficulties, and hypervigilance. Hypervigilance is an excessive concern for the safety and well-being of oneself or others. An exaggerated startle response, or a tendency to overreact to loud noises or unexpected stimuli, can also develop.

PREVALENCE

Data regarding the rates of PTSD outside the United States are limited. Although there is a paucity of large-scale epidemiological research on prevalence rates in other countries, available information suggests that PTSD is most prevalent in postconflict, economically disadvantaged, war-torn countries with high rates of social conflict and mass violence (Duke & Vasterling, 2005). DeJong and colleagues (2001) found rates ranging from 15.8% in Ethiopia to 37.4% in Algeria.

Rates of PTSD in the United States, primarily from the Epidemiological Catchment Area Study, the first large-scale study of the prevalence of psychiatric disorders in the general population conducted in five American cities, are low in comparison to non-Western countries. The *DSM-IV-TR* cites prevalence estimates from 1% to 4% (American Psychiatric Association, 2000). Breslau, Davis, Andreski, and Peterson (1991) reported a rate of 9% (11% for women, 5% for men) in the general population. Breslau et al. also found that nearly 40% of the sample had experienced one or more traumatic event in their lifetime. Although the Epidemiological Catchment Area Study has been widely praised for its methodological procedures and adherence to key standards in survey research, it has been criticized by scholars and experts as underestimating the rates of PTSD (Keane & Barlow, 2002).

The National Comorbidity Survey (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995) was another attempt to provide a comprehensive national estimate of PTSD. Kessler and colleagues interviewed a nationwide sample of 5,877 individuals and found an overall prevalence rate of 8%, with the rate of PTSD in women more than twice that of men (10% vs. 5%). The survey also demonstrated unequivocally that trauma exposure is a relatively frequent life event, in that 61% of men and 51% of women reported experiencing at least one traumatic event during their lifetime.

The most comprehensive examination of the prevalence of PTSD among combat veterans comes from the National Vietnam Veterans Readjustment Study

(Kulka et al., 1990). The study, a congressional mandate, was the first time—although certainly not the last—that government sought to systematically understand the psychological costs of participation in war. The study examined three groups of individuals: Vietnam veterans ($n = 1,632$), other veterans of the same era ($n = 716$), and nonveterans ($n = 668$) matched on important variables, such as age, sex, race, and ethnicity. Results indicated that more than 15% of male Vietnam veterans met criteria for current PTSD and approximately 30% met criteria for PTSD in their lifetime. Over 8% of female veterans met criteria for current PTSD and roughly 27% met criteria for lifetime PTSD. These rates were 5–10 times higher than rates found among comparable veterans of the same era and nonveterans. Rates of PTSD among more recent conflicts have ranged from 4% to 19% (see reviews by Keane & Barlow, 2002; Norris & Slone, 2007). Although large-scale longitudinal studies examining the impact of combat on Operation Iraqi Freedom and Enduring Freedom veterans have yet to be completed, preliminary estimates indicate high rates of PTSD among returnees. An anonymous survey administered to returning troops found that approximately 12% of Iraq-deployed veterans met conservative criteria for PTSD based on a symptom checklist, whereas 6% of veterans from Afghanistan met diagnostic criteria for PTSD (Hoge, Castro, Messer, McGurk, Cotting, & Koffman, 2004).

Traumatic events are fairly common in the general population; however, rates of PTSD are much lower, with community estimates ranging from 3% to 11%. Rates are higher among at-risk populations, including combat veterans and communities affected by mass violence or natural disasters.

COURSE

PTSD can occur at any age, including early childhood (Scheeringa, Zeanah, Myers, & Putnam, 2005). In adults, symptoms typically begin within the first 3 months after the trauma, although there can be delays of months or years before symptoms appear (i.e., delayed-onset PTSD). Many individuals experience some symptoms of post-traumatic stress immediately following a traumatic event, such as reexperiencing the trauma through intrusive thoughts and nightmares, loss of interest or pleasure in usual activities, difficulty sleeping, and being easily startled. Many of these symptoms improve over time without clinical intervention. For example, Galea and colleagues (2002) found that approximately

20% of individuals living in the vicinity of the World Trade Center met criteria for probable PTSD and 7% of Manhattan residents met probable criteria for PTSD. However, 6 months later, a much lower percentage (less than 1%) of Manhattan residents met probable diagnostic criteria for PTSD.

The clinical symptoms and the relative predominance of reexperiencing, avoidance, and hyperarousal symptom clusters may vary over time. The pattern of PTSD symptom expression often fluctuates with life stress and exposure to traumatic reminders. When PTSD symptoms occur, many experience a full recovery—with symptom remission occurring within 3 months in approximately half of all cases (American Psychiatric Association, 2000). However, PTSD can persist for years, and many individuals with long-term symptoms meet criteria for chronic PTSD, defined as lasting 3 months or longer. Approximately one-third of PTSD-diagnosed individuals in the National Comorbidity Survey reported persistent symptoms 10 years post-trauma, even among those who had received psychiatric treatment. Fifteen percent of combat veterans in the National Vietnam Veterans Readjustment Study still suffered from PTSD over 19 years later (Kulka et al., 1990).

COMORBIDITY

When PTSD is diagnosed, it often occurs concomitantly with other conditions. Clinical and community studies have demonstrated that people with PTSD frequently meet diagnostic criteria for multiple psychiatric disorders, particularly affective disorders, other anxiety disorders, and substance use disorders (see Brady, Killeen, Brewerton, & Lucerini, 2000, for a review; Keane & Wolfe, 1990).

When examining other current and lifetime anxiety and unipolar mood disorders, Brown, Campbell, Lehman, Grisham, and Mancill (2001) reported that among a sample of 1,127 psychiatric community-dwelling outpatients, those with PTSD showed the most severe and diverse pattern of comorbidity. Seventy-seven percent of the patients in the study met criteria for major depression. Shalev (2001) reviewed the literature and found that concurrent rates of major depression among individuals with PTSD ranged from 30% to 50%, with rates potentially higher among those seeking treatment. Franklin and Zimmerman (2001) examined whether symptom overlap between major depression and PTSD (i.e., anhedonia, concentration problems, sleep difficulties) could be responsible for the high rates of comorbidity in 1,300 psychiatric patients with a lifetime history of

PTSD. They concluded that the comorbidity between the disorders was not an artifact of symptom overlap and represented unique symptomatology. Depression is a frequent presenting problem among individuals with PTSD that can affect assessment and treatment and, as such, needs to be carefully evaluated and monitored.

Anxiety disorders frequently co-occur with PTSD. In the National Comorbidity Survey, comorbidity of PTSD with other anxiety disorders ranged from 15% (generalized anxiety disorder) to 29% (simple phobia) in women, and 7% (panic disorder) to 31% (simple phobia) in men (Kessler et al., 1995). In the Brown et al. (2001) study, 38% of PTSD patients met criteria for generalized anxiety disorder, 31% for obsessive-compulsive disorder, 23% for specific phobia, 23% for panic disorder with agoraphobia, and 15% for social phobia.

Individuals with PTSD also frequently have alcohol and other substance use problems. Lifetime prevalence of alcohol abuse/dependence and substance abuse/dependence among men with a history of PTSD in the National Comorbidity Survey was approximately 52% and 35%, respectively (Kessler et al., 1995). Among women with PTSD, rates were slightly lower, although still fairly high, at 28% and 27%, respectively (Kessler et al., 1995).

Physical health problems are frequently seen among trauma-exposed individuals (see Schnurr, Green, & Kaltman, 2007). Evidence of the relationship between trauma exposure, PTSD, and self-reported health problems comes from large and diverse samples of community-dwelling members, veterans, and military personnel. There is also a wealth of evidence derived from special populations, such as individuals who have experienced sexual assault, adults with a history of childhood trauma, and older adults (e.g., Buckley, Green, & Schnurr, 2004; Schnurr, Spiro, & Paris, 2000). National studies indicate that veterans with PTSD tend to report more physical health problems and rate their health more poorly than veterans without PTSD (Centers for Disease Control, 1988; Kulka et al., 1990). Schnurr, Spiro, and Paris (2000) employed objective mediators of health to examine the role of PTSD in a sample of Korean War and World War II veterans and found that level of combat exposure predicted the onset of several physician-diagnosed medical conditions. Individuals who have been exposed to a traumatic event also tend to use more medical services than those without a history of trauma (Schnurr, Friedman, Sengupta, Jankowski, & Holmes, 2000b; see Walker, Newman, & Koss, 2004). Individuals with PTSD also demonstrate higher rates of adverse health behaviors, such as smoking, substance use (Shalev, Bleich, & Ursano, 1990),

and high-risk behaviors (e.g., suicide, accidents), as well as higher rates of cardiovascular disease even after for behavioral risk factors have been controlled for (Kubzansky, Koenen, Spiro, Vokonas, & Sparrow, 2007). There is some evidence that trauma exposure may be related to increased mortality (Buckley et al., 2004; see Schnurr, Green, & Kaltman, 2007), although causal mechanisms underlying this phenomenon need to be further delineated.

PTSD and its comorbidities present real and significant challenges for practitioners. Clinically, individuals with PTSD and a comorbid psychiatric disorder present with more severe PTSD symptoms and a poorer response to treatment (see Friedman et al., 2007, for a review).

NEUROBIOLOGICAL ALTERATIONS IN PTSD

Life-threatening events and fear mobilize complex biological systems involving multiple brain regions and hormonal and neurotransmitter systems. These systems are well suited to prepare biological organisms to respond to immediate threats in their environment and serve important biological and adaptive functions. Dysregulation of multiple neurobiological systems clearly plays an important role in the pathophysiology of PTSD and will be discussed in the following sections. The review of findings presented here is not exhaustive and does not purport to cover all the biological findings (e.g., brain imaging, neurotransmitters, neuropeptides, neuroimmunological, and neuroendocrine) associated with PTSD. Rather, this discussion is intended as a general overview of the key neurobiological alterations in PTSD, with particular attention to those deemed to have relevant clinical and treatment implications. Findings are summarized in Table 14.2.

The Hypothalamic-Pituitary-Adrenal Axis

The hypothalamic-pituitary-adrenal (HPA) axis plays a central role in the stress response (see Bremner, Southwick, & Charney, 1999; Nemeroff & Schatzberg, 1988, for extensive reviews). Figure 14.1 presents a brief overview of the major components of the HPA axis. While the sympathetic nervous system is tied to preparatory action, the HPA axis appears to facilitate defensive responding as well as restoration of homeostasis (Munck,

Guyre, & Holbrook, 1984; Southwick, Vythilingam, & Charney, 2005; Yehuda, 2002).

Glucocorticoids and Catecholamines

The neuroendocrine system is an important biological substrate implicated in PTSD. Given the role that hormones, particularly the glucocorticoids and catecholamines, play in the normal stress response, it is no surprise that a considerable amount of research on these neurohormonal mechanisms has been generated over the past two decades. Glucocorticoids are central in the expression of stress responses, such as increased gluconeogenesis, inhibition of growth and reproductive systems, and containment of inflammatory responses.

Researchers originally hypothesized that elevated levels of glucocorticoids, primarily cortisol, would be found in the brains of individuals with PTSD; however this has not been borne out. In fact, despite the hypersecretion of corticotropin-releasing factor typically found among those with PTSD, normal to low baseline levels of cortisol (Yehuda, 2002) and greater number of glucocorticoid receptors (Yehuda, Lowy, Southwick, Shaffer, & Giller, 1991) are generally found. The potential importance of increased glucocorticoid receptor responsiveness in some brain structures is that their presence could represent a heightened negative feedback system, accounting for an overall decrease in peripheral cortisol and a heightened suppression of cortisol compared to controls (Bremner, Davis, Southwick, Krystal, & Charney, 1995). Several longitudinal studies demonstrate the relationship between cortisol levels and the development of PTSD after various types of trauma. Individuals who developed PTSD following a motor vehicle accident had lower levels of cortisol immediately post-trauma (Yehuda, McFarlane, & Shalev, 1998). Women with a prior history of sexual assault who had been raped had lower levels of cortisol than women with no trauma history. Individuals with PTSD differ from individuals with a primary diagnosis of major depression, in terms of findings from the dexamethasone suppression test. Dexamethasone is a synthetic steroid similar to cortisol that suppresses adrenocorticotropin secretion in normal healthy individuals. In individuals with PTSD, an enhanced suppression (i.e., lower levels) of cortisol is generally found, particularly in the low dose test (i.e., 0.5 mg) (Yehuda, 2002).

This line of research, coupled with findings from the animal stress literature, has led some to postulate that enhanced negative feedback and HPA reactivity may be

14.2

Key Neurobiological Findings in PTSD

HPA AXIS

Glucocorticoids

- Abnormal urine and plasma cortisol levels
- Increased number of lymphocytic glucocorticoids
- Exaggerated cortisol suppression to dexamethasone
- Increased cortisol response to CRH and ACTH

Catecholamines

- Exaggerated epinephrine and NE responses to traumatic reminders
- No evidence for increased NE under baseline/resting conditions
- Increased 24-hour plasma NE levels
- Increased 24-hour urine NE excretion

SEROTONIN

- Decreased platelet serotonin uptake
- Blunted prolactin response to d-fenfluramine
- Exaggerated response to serotonergic probes
- Clinical response to SSRIs

PSYCHOPHYSIOLOGICAL

- Cardiovascular reactivity to traumatic stimuli
- Galvanic skin conductance response to traumatic stimuli
- No differences when examining resting indices
- Reduced ERPs to stimuli of increasing intensity
- Reduced habituation and larger ERPs to novel or traumatic stimuli

Figure 14.1 Major components of the hypothalamic-pituitary-adrenal (HPA) axis.

In response to acute and chronic stress, the paraventricular nucleus of the hypothalamus secretes corticotropin-releasing factor (CRF), which, in turn, stimulates the anterior pituitary gland to synthesize and release adrenocorticotropin (ACTH). ACTH stimulates the synthesis and release of cortisol from the adrenal glands. Cortisol, an important stress hormone, is responsible for mobilizing and replenishing energy reserves, inhibiting growth and reproductive systems, containing the immune response, and affecting behavior through its action on multiple neurotransmitter systems and brain areas.

related to individual differences in the development of PTSD and function as a preexisting risk factor or critical pathway related to certain types of early experiences and changes in brain morphology (Yehuda, 2002).

Exaggerated noradrenergic activity in individuals with a history of trauma and diagnosis of PTSD has been observed across a large number of physiological, neuroendocrine, brain-imaging, and other biological modalities. Preclinical studies demonstrate that central noradrenergic nuclei play an important role in orientation to novel stimuli, alertness, vigilance, selective attention, and cardiovascular responses to life-threatening stimuli (Aston-Jones, Rajkowski, Kubiak, & Alexinsky, 1994). The locus coeruleus contains the majority of noradrenergic cell bodies in the brain (Zigmond, Finlay, & Sved, 1995). Another brain region involved in the detection of threatening stimuli and defensive responding is the amygdala. The catecholamines play a central role in the encoding and consolidation of memory for events and stimuli that are arousing, stressful, or fear inducing. It has been well established in numerous animal and human studies that the administration of epinephrine or norepinephrine enhances memory consolidation and retention (see Southwick, Rasmusson, Barron, & Arnsten, 2005, for a cogent review). The release of catecholamines in response to traumatic events has been postulated to be an enhancing memory formation and related to reexperiencing of the trauma through intrusive thoughts and distressing memories (McNally, 2003b).

Noradrenergic overreponsivity to a variety of stressors, particularly trauma-relevant stimuli, has been demonstrated across a number of clinical physiological, neuroendocrine, receptor-binding, pharmacological challenge, neuroimaging, and pharmacological treatment studies (Southwick, Bremner, et al., 1999). However, noradrenergic hyperreactivity has not been found at baseline or under resting conditions. In other words, under general non-stress conditions, individuals with and without PTSD do not demonstrate differences in baseline levels of norepinephrine. This contrasts with results obtained through the use of measures of 24-hour plasma and urine catecholamine levels. Most 24-hour urine excretion studies have found higher levels of norepinephrine in trauma survivors with PTSD than in controls (Southwick, Bremner, et al., 1999). Plasma norepinephrine levels have also been found to differ among individuals with PTSD and healthy controls (Southwick, Bremner, et al., 1999). It has been suggested that the 24-hour sampling procedure represents the summation of phasic physiological changes in response to both meaningful stimuli and tonic resting

catecholamine levels, whereas baseline measures only capture tonic activity (Friedman et al., 2007; Southwick, Paige, et al., 1999).

Serotonin

Serotonin (5-hydroxytryptamine, or 5-HT) is a monoamine neurotransmitter that is implicated in numerous mood disorders and has excitatory and inhibitory actions in the central nervous system. Neurons that synthesize and release serotonin are found almost exclusively in the raphe nuclei of the brain stem (Nestler, Hyman, & Malenka, 2001).

Direct evidence for 5-HT dysregulation in PTSD comes from multiple lines of research, including clinical studies of traumatized individuals and neuroendocrine challenge paradigms. Resting decreased platelet serotonin uptake, blunted prolactin response to the serotonin-releasing and uptake inhibitor d-fenfluramine, and exaggerated panic response to serotonergic probes have all been demonstrated in PTSD subjects compared to non-affected individuals (see Friedman et al., 2007).

The relationship between trauma-related psychopathology and 5-HT activity is likely mediated by both cortical and subcortical brain regions. Particular brain regions regulated by 5-HT that have been implicated in the pathophysiology of PTSD are the prefrontal cortex, amygdala, locus coeruleus, and hippocampus. The orbitofrontal cortex, which is particularly sensitive to the effects of serotonin (Park, Coull, McShane, Young, Sahakian, Robbins, & Cowen, 1994), is known for its role in filtering and processing social and emotional information and has been associated with a number of symptoms of PTSD, including impulsivity, aggression, and emotional information-processing differences (Vasterling, Brailey, Constans, & Sutker, 1998).

The strongest clinical evidence for the role of 5-HT in PTSD is found in pharmacological studies. Research involving the gold-standard research design in pharmacology, the double-blind, randomized, placebo-controlled clinical trial, indicates that the selective serotonin reuptake inhibitors (SSRIs) have been shown to be more effective than placebo (Stein, Ipser, & Seedat, 2005) and to ameliorate the primary symptom clusters of PTSD (avoidance, reexperiencing, hyperarousal). Other classes of medications, including the monoamine oxidase inhibitors and tricyclic antidepressants, which inhibit presynaptic serotonin reuptake, have also proved effective in treating PTSD symptoms, although the SSRIs are considered first-line agents in the pharmacological treatment of PTSD (Friedman & Davidson, 2007).

PSYCHOPHYSIOLOGY

Research involving combat veterans has demonstrated that heightened physiological arousal to trauma-related cues influenced the development of the diagnostic criteria for PTSD (Rabois, Batten, & Keane, 2002). Hypervigilance, physiological reactivity, and an exaggerated startle response are cardinal features of the disorder, which makes psychophysiological assessment a relevant focus for the study and treatment of trauma-related disorders. Research examining the physical reactivity of individuals with and without PTSD to traumatic cues has consistently demonstrated that on average, individuals with the disorder exhibit greater levels of reactivity than control subjects. This finding has been replicated across various groups, including combat veterans (Vietnam, Korea, World War II) and nonveteran populations (for a comprehensive review of this literature, see Orr, Metzger, & Pittman, 2002). The largest and most methodologically rigorous study of this type was conducted by the Department of Veteran Affairs (Keane et al., 1998) and demonstrated that combat veterans with PTSD show heightened physiologic arousal when exposed to trauma-related cues. Keane and colleagues were able to classify approximately two-thirds of individuals with PTSD using a combination of four physiological variables (heart rate, skin conductance, blood pressure, and electromyogram activity).

There is evidence, although slightly less consistent, for baseline cardiovascular reactivity among individuals with PTSD. When compared with control subjects, individuals with PTSD exhibit consistently higher heart rates. However, when compared with individuals with other anxiety disorders or those that have been exposed to trauma who do not have PTSD, results have been mixed (see Rabois et al., 2002, for a cogent review). Buckley and Kaloupek (2001) concluded based on their recent meta-analysis comparing individuals with PTSD to a traumatized group without PTSD that PTSD is associated with elevated levels of basal heart rate and diastolic blood pressure. This finding was still apparent even after differences in anticipatory anxiety were considered.

Basal heart-rate and heart-rate responsiveness has also been shown to be predictive of PTSD development. Results from several studies suggest that basal cardiovascular activity is elevated in response to trauma-related stimuli and that these differences are observed shortly after trauma exposure (Orr et al., 2002). Studies reviewed by Orr and colleagues demonstrate that individuals who developed PTSD following a traumatic

accident had significantly higher post-trauma resting heart rates, but not blood pressure levels.

Event-Related Brain Potentials

Event-related brain potentials (ERPs) are electrical changes recorded on the surface of the scalp in response to specific stimuli. ERPs are measured through the use of an electroencephalogram; electrodes are placed on the surface of the scalp to record and amplify the brain's neuronal activity. Over the past decade, ERP studies have been increasingly conducted among individuals with PTSD to examine cognitive activity (such as the ability to focus on information as well as ignore or filter irrelevant stimuli). Although this type of research is in its early stages, there are several important findings to consider. First, combat veterans with PTSD have a unique response to increasingly intense stimuli. Most individuals evidence increasing brain-wave amplitudes when presented with progressively louder auditory stimuli, although Paige, Reid, Allen, and Newton (1990) found that 75% of PTSD veterans evidence decreasing amplitudes in response to such stimuli. In contrast, 83% of veterans without PTSD show the more prototypical pattern (i.e., increased amplitude in response to stimuli increasing in auditory intensity). In research examining habituation to recurring stimuli, PTSD veterans exhibit less habituation to a second presentation of an auditory stimulus than combat-exposed veterans without PTSD (Gillette et al., 1997; Neylan et al., 1999). Reduced suppression has been found across a number of psychiatric disorders but has been postulated to be related to reduced sensory gating and an impairment in the ability to filter out irrelevant sensory information in individuals with PTSD (Orr et al., 2002).

Findings from psychophysiological studies support disturbances in the processes of attention and information processing among individuals with PTSD. It is clear that there are complex neurobiological alterations in PTSD and that these neurobiological findings are central to the development and expression of PTSD symptoms.

PSYCHOPHARMACOLOGY

Significant advances in the neurobiology of PTSD and a growing understanding of the pathophysiology of traumatic stress have led to significant developments in the field of clinical psychopharmacology (Friedman & Davidson, 2007). Science has yet to develop a pharmacological agent specific to PTSD. However, the past decade has witnessed the growth of an empirical database

for evidence-based treatment and rational pharmacotherapy for PTSD (Friedman & Davidson, 2007; see Table 14.3). The medications currently used to treat PTSD were originally developed to treat other clinical conditions and later found to be effective in treating PTSD symptoms (Friedman, Donnelly, & Mellman, 2003). The symptom overlap among the anxiety and depressive disorders, as well as research demonstrating the efficacy of antidepressant medications for the treatment of anxiety disorders, has led researchers to theorize that the disorders share similar etiologies and pathophysiology (Williams, Watts, MacLeod, & Mathews, 1997).

As previously mentioned, psychopharmacological research in PTSD has focused predominantly on sero-

tonergic mechanisms (Friedman & Davidson, 2007). Selective serotonin reuptake inhibitors (SSRIs) are a class of antidepressant medications that work by increasing levels of serotonin (5-HT) in the brain. There are currently two SSRIs that have received approval from the United States Food and Drug Administration for the treatment of PTSD—sertraline and paroxetine (Friedman et al., 2003). Both drugs have been shown to significantly reduce PTSD symptoms when compared to placebo (e.g., Brady, Pearlstein, et al., 2000; Marshall, Beebe, Oldham, & Zaninelli, 2001). In studies evaluating SSRIs specifically, treatment effect sizes for pharmacologic agents were smaller than those observed in psychotherapy trials (Brady, Pearlstein, et al.,

14.3

Medication Indications for PTSD and Related Problems

MEDICATION CLASS	NO. OF RCTs	DSM-IV-TR SYMPTOM CRITERIA	OTHER INDICATIONS
SSRI	6	B, C, D	Depression, panic, social phobia, and obsessive-compulsive disorders
Other antidepressants ^a	4	B, C, D	Depression
MAOI	1	B	Depression, panic, and social phobia
Antiadrenergic agents	2	B, D	
Anticonvulsants	1	B, C, D	Cognition and bipolar disorder
Benzodiazepines ^b	1	D	General anxiety and insomnia
Atypical antipsychotics	4	B, D	Aggression, psychotic symptoms

^aVenlafaxine accounts for two of these RCT. ^bUsed as an adjunctive agent.
Note: SSRI = selective serotonin reuptake inhibitor; MAOI = monoamine oxidase inhibitor; RCT = randomized controlled trial.

Adapted from Friedman, Donnelly, & Mellman, 2003; and *Handbook of PTSD: Science and Practice*, by M. J. Friedman, T. M. Keane, & P. A. Resick, 2007. New York: Guilford Press.

2000; Keane & Barlow, 2002), even though they were successful at reducing PTSD symptoms and were well tolerated by patients. Future research comparing psychotherapy, pharmacotherapy, and the combination of psychotherapy and pharmacotherapies has been called for by scholars and leading clinicians in the field (Keane & Barlow, 2002).

Other types of medications for treating PTSD have not been investigated to the same extent as the SSRIs. For example, the only non-SSRI medication to have been evaluated in more than one randomized controlled trial (RCT) for treatment PTSD is venlafaxine, a second-generation antidepressant (see Friedman & Davidson, 2007, for an extended review of RCTs in PTSD). However, non-SSRI agents are used because they treat specific symptoms experienced by individuals with PTSD with some success. For example, the antidepressant trazodone has been used as an adjunct to treatment with other SSRIs to reduce insomnia (Friedman & Davidson, 2007). In addition, antiadrenergic agents (e.g., prazosin) have been used to reduce traumatic nightmares (Raskind et al., 2003; Taylor et al., 2008) and non-nightmare distressed awakenings (Thompson, Taylor, McFall, Barnes, & Raskind, 2008). Anticonvulsants (e.g., gabapentin, lamotrigine, carbamazepine, valproate) have also been used with some success, but no RCTs have been conducted to date (Friedman & Davidson, 2007). Atypical antipsychotic agents (i.e., olanzapine and risperidone) have also been used to treat target symptoms such as hypervigilance/paranoia, physical aggression, social isolation, and hallucinations (Friedman et al., 2003); however, these agents are used rarely, and then only in patients who have failed to respond to other medications (Foa, Keane, & Friedman, 2000). While benzodiazepines do not have specific effects on PTSD symptoms, they have been shown to improve sleep and reduce general anxiety (Braun, Greenberg, Dasberg, & Lerer, 1990). In general, they are not recommended for individuals with PTSD due to the potential for substance dependence and withdrawal following discontinuation.

Friedman et al. (2003) outline several guidelines for the rational use of medications for PTSD. They caution that there are no hard and fast rules, but that medication choice should be tailored to the individual's needs and informed by several considerations. They suggest implementing pharmacotherapy in situations in which (1) patients are open to psychopharmacological treatment for PTSD, (2) there is comorbid psychopathology, (3) symptom severity is interfering with psychotherapy for PTSD or comorbid conditions, and (4) psychotherapeutic treatment alternatives are not available.

PTSD ASSESSMENT

Diagnosing PTSD can be complex due to a number of factors, including (1) the total number of symptoms that warrant the diagnosis, (2) the complicated criterion sets that must be met, and (3) the medicolegal context inherent in the disorder, particularly in situations related to secondary gain or potential denial of financial resources or access to benefits, goods, or services. Fortunately, there are a number of reliable and valid measures of trauma and PTSD available to clinicians to facilitate accurate diagnoses. Measures are typically broken down into structured and semi-structured interviews to evaluate PTSD symptoms, self-report assessments of trauma exposure and PTSD symptoms, measures of a patient's approach to the testing procedure (response style), and psychophysiological measures. In choosing a specific assessment approach, clinicians should take into account the referral question and the feasibility of applying a particular method with the patient.

PTSD Diagnostic Interviews

Diagnostic interviews for PTSD typically include the assessment of pretrauma, peri-trauma, and post-trauma functioning (see Table 14.4). Pretrauma variables include the individual's social, academic, and family functioning before the traumatic event and an assessment of early stressors or any preexisting trauma. Peri-traumatic information is collected about the traumatic event and the individual's reaction in order to ensure Criteria A1 and A2 are met. Other relevant information is gathered, such as whether the individual is capable of recalling details of the trauma (e.g., was the individual rendered unconscious, was there impairment due to substances, was extreme dissociation present?). Post-trauma variables are factors that must be taken into consideration that occur following the trauma. Variables to evaluate are those that result in functional impairment in major life roles (e.g., social, occupational/academic, self-care) or reductions in overall quality of life.

As mentioned in the introduction, PTSD is unique in that it is one of only two disorders in the *DSM-IV* (American Psychiatric Association, 2000) that requires that emotional symptoms be linked to a precipitating event. Additionally, because PTSD is frequently present along with a number of comorbid or co-occurring disorders, it is important that the symptoms observed be causally linked to the trauma. Therefore, the goal of assessment is to document symptom development and

14.4

Components of a Typical
PTSD Interview

Pre-trauma Variables	Stressful events
	Traumatic events
	Psychological symptoms
	Occupational functioning
	Social functioning
Peri-trauma Variables	Traumatic event (Criterion A1)
	Emotional reaction to the traumatic event (Criterion A2)
	Other pertinent information about traumatic event or related circumstances
Post-trauma Variables	PTSD symptoms related to index trauma
	Other current psychological symptoms
	Occupational functioning
	Social functioning
	Methods/means of coping
	Additional traumatic events
	Current stressors

establish a link either temporally or conceptually to the traumatic life event. Therefore, it is essential that the onset of the observed symptoms occurs subsequent to the trauma or that the symptoms are linked to the trauma via some theoretical mechanism. For example, if emotional numbing did not begin immediately after the traumatic event, the diagnosing clinician must closely evaluate the patient's history, taking into account relevant post-trauma variables (e.g., coping methods, additional stressors) to determine whether delayed symptom development is plausible and based on the overall history and formulation. Accurate and comprehensive assessment by a knowledgeable clinician familiar with PTSD is essential to establish a reliable diagnosis.

Assessment Instruments

Psychological assessment instruments can be used to augment and enhance the reliability of traditional assessments. Assessment instruments for PTSD generally fall into two categories: (1) trauma exposure measures and (2) PTSD symptom measures. The choice of which particular instrument depends on the context and purpose of the PTSD assessment as well as the overall balance of reliability, validity, sensitivity, and specificity of the measure being considered.

Trauma Exposure Measures

Individuals with PTSD often have a history of multiple traumas. A measure of trauma exposure can assist the patient and the clinician to focus on the individual's lifetime history of trauma. Trauma exposure measures are useful because they can rapidly access a wide variety of traumatic life events and quickly identify an individual's level of involvement in the event. For example, the Life Events Checklist (Blake et al., 1990), one of the most commonly used trauma exposure measures, queries whether 17 potentially traumatic events, such as natural disasters, fire or explosions, and assault with a weapon, have happened over the course of the individual's entire life. The checklist also asks individuals to indicate whether these events happened directly to them, were witnessed, or were learned about secondhand.

There are no self-report trauma measures that assess for the *DSM-IV* definition of a traumatic event, because no instruments query the individual on Criterion A2 (whether they experienced fear, helplessness, or horror). However, there are several measures that query threat to one's life and whether the individual perceived the event as traumatic. These include the Trauma Assessment for Adults (Resnick, Falsetti, Kilpatrick & Freedy, 1996), the Traumatic Events Questionnaire (Vrana & Lauterbach, 1994), and the Traumatic Stress Scale (Norris, 1990).

PTSD Symptom Measures

PTSD symptom measures are divided into self-report and interview-based instruments. Self-report measures are often screening instruments that do not provide a definitive PTSD diagnosis. As screening measures, these instruments often sacrifice specificity (ability to identify people without the disorder) for high sensitivity (ability to identify people with the disorder). Measures that have a high false-positive rate (classifying individuals as having the disorder when they do not)

ensure that few patients with PTSD will be missed. Results of self-report measures should be further evaluated by a clinician before a diagnosis is rendered. The advantages of using self-report measures is that they provide a quick look at potential threshold PTSD symptoms, take minimum amount of the patient's time and effort, and are easily scored against normative data. They are also a useful way for providers to quickly track symptom change across treatment sessions. Examples of self-report symptom measures include the PTSD Diagnostic Scale (Foa, Cashman, Jaycox, & Perry, 1997), PTSD Checklist (Weathers, Litz, Herman, Huska, & Keane, 1993), and the Impact of Events Scale (Weiss & Marmar, 1996).

Interview-based measures of PTSD provide a more detailed assessment of symptoms, leading to a definitive diagnosis. The Structured Clinical Interview for *DSM-IV* (SCID; First, Spitzer, Gibbon, & Williams, 1996) PTSD module is a structured interview that evaluates individual PTSD symptoms using a structured series of ques-

tions targeting specific symptoms. The gold standard of interview-based PTSD assessments is the Clinician-Administered PTSD Scale (Blake et al., 1995), which has well-established psychometric data. It is unique in that it is the only measure that queries about both symptom frequency and intensity, using behaviorally specific anchors for clinician ratings (Elhai, Gray, Kashdan, & Franklin, 2005). This type of inquiry leads to a more detailed understanding of each PTSD symptom reported. The Clinician-Administered PTSD Scale also provides several different scoring methods, depending on the nature and purpose of the assessment, including an overall score and various cut scores based on scores on frequency and intensity, leading to varying levels of sensitivity and specificity in diagnosing PTSD (Weathers, Ruscio, & Keane, 1999).

Elhai and colleagues (2005) examined the frequency with which PTSD assessment tools were used in a representative sample of 565 members of the International Society for Traumatic Stress Studies via an

14.5 | Commonly Used Assessment Instruments

TRAUMA EXPOSURE		PTSD SYMPTOM	
INTERVIEW-BASED	SELF-REPORT	INTERVIEW-BASED	SELF-REPORT
Evaluation of Lifetime Stressors (ELS)	Post-Traumatic Diagnostic Scale (PDS)	Clinician-Administered PTSD Scale	Trauma Symptom Inventory (TSI)
National Women's Study PTSD Module	Life Events Checklist (LEC)	Structured Clinical Interview for DSM-IV–(SCID) PTSD module	PTSD Checklist (PCL)

Traumatic Stress Schedule (TSS)	Conflict Tactics Scale (CTS)	Diagnostic Interview Schedule–(DIS) PTSD module	Impact of Event Scale–Revised (IES-R)

Note: Data was collected from 227 ISTSS members. Information on these instruments can be obtained from the Web site maintained by the National Center for PTSD (www.ncptsd.org).

e-mail survey. They asked members, of whom 227 responded, to rank the trauma exposure and PTSD symptom assessments they used most frequently for clinical and research purposes. The study did not find significant agreement among experts on commonly used adult trauma exposure interviews. Table 14.5 provides a summary of their findings, along with a list of the most commonly used interview-based measures from the National Center for PTSD (see National Center for PTSD, n.d.).

Overcoming Bias in PTSD Assessment

The assessment of PTSD can be fraught with incentives to over- or underreport psychopathology, depending on the assessment context. Therefore, in some contexts, particularly in the medicolegal arena, it is important to either use a non-biased indicator of PTSD or collect data on the patient's response style to inform the interpretation of assessment data.

Measuring a patient's approach to the test-taking situation allows response style factors to be taken into account during a clinical interview. Few PTSD symptom assessment measures include a measure of response style. The Trauma Symptom Inventory (Briere, 1995) queries for general malingering along with symptoms that correspond but are not specific to PTSD. However, Elhai and colleagues (2005) did not find overall utility for the Trauma Symptom Inventory in the detection of malingered PTSD. The MMPI-2 has scales that evaluate over- and underreporting of symptoms, along with affirmative and negative (yes and nay-saying) approaches. The MMPI-2 has two scales originally thought to be specific to PTSD: the PK (Keane, Malloy & Fairbank, 1984) and PS (Schlenger & Kulka, 1987) scales. Much research has been done with these scales, the findings of which demonstrate that neither consistently discriminates between PTSD and general psychological distress (Greene, 2000). The most empirically validated measure of response style in forensic contexts, the Structured Interview of Reported Symptoms (Rogers, Gillis, Dickens, & Bagby, 1991), has not been well researched or validated for use with PTSD.

Psychophysiological measures have been of interest to researchers seeking a non-biased indicator of the presence of PTSD and are tied closely to empirical data on the psychophysiology of PTSD discussed earlier. Psychophysiological measures are thought to be good indicators of PTSD because of the features of hyperarousal inherent in the disorder and the lack of reliance on self-report data. In psychophysiological assessment, pa-

tients are shown depictions of trauma-relevant stimuli, and their physiological response (i.e., heart rate, muscle tension, skin conductance) is measured. As previously discussed, research in this area has demonstrated the ability of psychophysiological measures to identify differences between individuals with and without PTSD (Orr & Roth, 2000), particularly among individuals who do not take antianxiety medications, since they can artificially reduce arousal. However, at the present time, using psychophysiological measures for general assessment purposes is untenable for most clinicians. The financial cost of the measures, time constraints on the clinician, and patient burden may ultimately outweigh their benefit. However, in the future, as technological advances become more integrated into clinical practice, such measures may become a more routine part of assessing PTSD.

PTSD TREATMENT

Research on the treatment of PTSD emerged in the late 1970s and early 1980s (Burgess & Holmstrom, 1974; Keane & Kaloupek, 1982). Today, most of the treatment outcome literature is on cognitive and behavioral therapies. Group psychotherapy and psychodynamic psychotherapy are regularly used to treat PTSD; however, the empirical support for these treatments is lacking (Foa et al., 2000). Psychodynamic therapies for PTSD may demonstrate poor efficacy because the goal of therapy is not symptom reduction. Therefore, it may be that those factors treated successfully by psychodynamic therapies (e.g., greater understanding of the meaning of the traumatic event) are not adequately reflected in the current research literature on empirically validated treatments for PTSD (Foa et al., 2000).

In 1997, the International Society for Traumatic Stress Studies established a task force of experts in the field of traumatic stress to establish treatment guidelines for PTSD. The results of this endeavor were initially presented in *Effective Treatments for PTSD: Practice Guidelines from the International Society for Traumatic Stress Studies* (Foa et al., 2000). More recently, in 2005, the society convened a body of members, the PTSD Treatment Guidelines Task Force, to update the initial set of guidelines and create a document outlining the current best practices in PTSD (Foa, Keane, Friedman, & Cohen, 2008). At the forefront of evidence-based therapies and best practices for PTSD are those that use a form of exposure therapy to reduce disturbing thoughts, feelings, and images.

Exposure-based therapies have a long and successful history in the treatment of anxiety disorders (Barlow, 1988). Exposure therapy can be imaginal or in vivo. Imaginal exposure attempts to reduce anxiety by having the patient imagine the feared situation object or event. In-vivo exposure therapy involves actually experiencing the feared situation, object, or event in order to reduce anxiety (e.g., returning to the site of the trauma or handling a feared object). There are several exposure-based therapies designed to treat PTSD specifically. These therapies are well researched and are described below.

Prolonged Exposure

Prolonged exposure therapy (PE; Foa & Rothbaum, 1998) was initially developed for rape survivors but is now more widely used for individuals who have experienced various types of trauma. PE combines the use of education, relaxation training, and flooding (i.e., rapid or intense exposure to a traumatic stimulus) to reduce PTSD symptoms. PE employs both imaginal and in-vivo exposure. Typically, in PE PTSD-diagnosed patients discuss traumatic events across nine sessions until their anxiety around the memory is reduced, signifying that the patient is habituated to the traumatic memory.

Studies find PE to be more effective than control conditions (Creamer & Forbes, 2004); however, the degree of benefit differs across studies and populations, with more effective symptom reduction found in civilians (Foa, Dancu et al., 1999; Resick, Nishith, Weaver, Astin & Feuer, 2002) than in veteran samples (Boudewyns, Hyer, Woods, Harrison, & McCrime, 1990). One of the most recent studies of PE (Schnurr et al., 2007) compared PE to a present-centered therapy among 284 female veterans. Results showed that while both treatments were well tolerated, the PE condition had a significantly higher dropout rate (58% vs. 21%) than the present-centered therapy. Both conditions showed significant reduction in PTSD clinician-rated symptom scores (based on the Clinician-Administered PTSD Scale) at the post-treatment assessment. While PE outperformed present-centered therapy at post-treatment, these results were not sustained at 3- and 6-month follow-up. In the study's intent-to-treat analysis (in which all participants were included, not just those who completed the full therapy protocols), self-reported symptoms of PTSD were lower for those who received PE than those who received present-centered therapy.

Recently, PE has been applied via virtual-reality computer programs. Rothbaum and colleagues (1999)

used virtual-reality exposure therapy with veterans from the Vietnam theater. While overall virtual-reality exposure was successful at reducing PTSD symptoms (Rothbaum, Hodges, Ready, Graap & Alarcon, 2001), it has been criticized for not being trauma specific enough to produce some change, accessible enough to be employed by clinicians, or generalizable to populations of PTSD patients other than combat veterans (Creamer & Forbes, 2004).

Eye Movement Desensitization Therapy

Eye movement desensitization therapy (EMDR; Shapiro, 1995) involves having patients imagine a traumatic scene while eye movements are induced by the therapist's fingers as they move across the individual's visual field. The movements are continuously repeated until the patient's anxiety is reduced, at which point the patient is instructed to generate an adaptive thought associated with the scene while again engaging in saccadic eye movements. The theory behind EMDR suggests that exposure to a traumatic event disrupts the physiological balance between excitatory and inhibitory systems in the brain, preventing successful processing and consolidation of the traumatic memory (Shapiro, 1991).

EMDR has been controversial since its inception (Tolin, Montgomery, Kleinknecht, & Lohr, 1995) as a result of how the theory was formed, early claims that it can reduce PTSD in a single session, and mixed empirical support. EMDR's founder, Francine Shapiro, published the first positive results in 1989, and a plethora of research investigations ensued. The results across studies demonstrate that EMDR has been found to be successful in reducing PTSD symptoms (Lee, Gavriel, Drummond, Richards, & Greenwald, 2002). However, studies comparing EMDR with other treatments (e.g., imaginal exposure) have not demonstrated the relative efficacy of EMDR over other exposure therapies (Rothbaum, Astin, & Marsteller, 2005). This suggests that the active component of EMDR may be exposure to traumatic memories. Eye movements, the unique component of EMDR, do not appear to be curative over and above the exposure itself, although the movements may serve as a distraction that allows the person to tolerate the exposure (Rogers & Silver, 2002). In addition, studies have not found that EMDR works any faster than exposure alone (Taylor, Thordarson, Maxfield, Fedoroff, Lovell, & Ogrodniczuk, 2003). Lastly, when researchers compared EMDR to a fixed eye movement condition (keeping eyes focused

straight ahead), they found no differences between treatment with and without the rapid eye movements (Deville & Spence, 1999; Pitman, Orr, Altman, Longpre, Poire, & Macklin, 1996). Shapiro (1995) has since suggested that eye movements in EMDR could be replaced with other lateral stereotypic movements (e.g., motor movements).

Proponents of the technique purport that the therapy involves more than simple exposure because patients are not limited to discussing the traumatic memory but instead are free to discuss any topic. In fact, this has only muddled the waters and has led some authors to suggest that EMDR may not be desensitization after all and may perhaps reflect the processes of adaptation, exposure, or habituation (Marin, 2007). Nevertheless, what is clear is that EMDR is an effective evidence-based treatment for PTSD, although clarification of the mechanisms by which EMDR produces symptom reduction is strongly needed to reduce the controversy surrounding the therapy (van Etten & Taylor, 1998).

Cognitive Processing Therapy

Cognitive processing therapy (CPT; Resick & Schnicke, 1992) combines anxiety management, cognitive restructuring, and exposure-based therapy to treat PTSD (Keane & Barlow, 2002). CPT is designed to alter maladaptive cognitive processes, such as assimilation (distorting memories of the trauma to fit prior beliefs) and overaccommodation (distorting beliefs to fit the trauma). It combines exposure therapy with cognitive restructuring and challenging cognitions in areas affected by PTSD (e.g., trust, self-esteem, intimacy, power). CPT differs from PE in that it focuses on exposing individuals to trauma-relevant beliefs, rather than promoting habituation to traumatic memories. Indeed research has shown that CPT with and without exposure to traumatic memories is effective in treating PTSD (Resick, Galovski, Uhlmansiek, Scher, Clum, & Young-Xu, 2008).

CPT was developed for the treatment of sexual assault survivors and has been shown to be effective across a number of studies (Ahrens & Rexford, 2002; Monson, Schnurr, Resick, Friedman, Young-Xu, & Stevens, 2006; Resick, Nishith, Weaver, Astin, & Feuer, 2002). CPT is now being applied to various types of trauma, and preliminary reports are encouraging (Ahrens & Rexford, 2002; Monson et al., 2006). CPT has been favorably compared to PE, both treatments having been found to be efficacious in reducing PTSD symptoms (Resick et al., 2002). However, there has been very little research

conducted with veteran samples. The sole study conducted with predominantly male Vietnam veterans (83%) with chronic PTSD found CPT to be more effective than a wait-list control condition in reducing PTSD reexperiencing and emotional numbing symptoms and associated symptoms such as depression, anxiety, social functioning, and guilt (Monson et al., 2006).

Skills-Based Therapies

The two most thoroughly investigated skills-based therapies for PTSD are anxiety management therapy (AMT) and stress inoculation therapy (SIT; Meichenbaum, 1974). Skills-based therapies teach patients how to cope with or manage their anxiety and fear through education, relaxation, breathing techniques, thought stopping, cognitive restructuring, guided dialogue, and role playing, among other skills.

Research demonstrates that skills-based therapies are effective for nonveteran PTSD-diagnosed individuals (e.g., sexual assault survivors; see Foa, Rothbaum, Riggs, & Murdoch, 1991) and PTSD veterans (see Chemtob, Novaco, Hamada, & Gross, 1997; Peniston, 1986). Foa, Dancu, Hembree, Jaycox, Meadows, and Street (1999) compared a wait-list control group to groups treated with AMT, exposure, and exposure with AMT. All three treatments effectively reduced PTSD symptoms in sexual assault survivors. Foa et al. (1991) compared exposure therapy to SIT, supportive counseling, and a wait-list control group. SIT outperformed supportive counseling and the wait-list conditions in reducing PTSD symptoms; however, exposure therapy was found to be superior to SIT.

Several studies have combined skills-based treatment with exposure therapy with good results. Frueh, Turner, Beidel, Mirabella, and Jones (1996) examined a combined treatment of exposure therapy, AMT, and cognitive therapy in a veteran sample, which yielded positive treatment effects. Fecteau and Nicki (1999) examined AMT combined with education, relaxation training, exposure, cognitive restructuring, and guided behavioral practice. This treatment combination was successful at reducing PTSD symptoms in motor vehicle accident survivors at post-treatment and 6-month follow-up.

Combined Treatment

Keane, Fisher, Krinsley, and Niles (1994) outlined a treatment for PTSD that combines effective approaches

to treating chronic and severe PTSD symptoms. Phases 1–6 are (1) behavioral stabilization, (2) education, (3) anxiety management training, (4) trauma focus, (5) relapse prevention, and (6) aftercare services. Fec-teau and Nicki (1999) assessed a phase-oriented individual psychotherapy approach similar to that proposed by Keane and colleagues. Results demonstrated that the approach was successful in reducing symptoms according to clinician-made and self-report ratings.

Emerging Treatments

Several evidence-based treatments to ameliorate PTSD symptoms currently exist. In addition, there are several other treatments that have recently emerged as promising preliminary treatment strategies, although further research is needed. One such treatment is imagery rehearsal therapy, which uses imagery-based group psychotherapy to reduce trauma-related nightmares. In imagery rehearsal therapy, patients write about a recurring nightmare (one that has the same content and occurs repeatedly), making a change to the dream. Patients rehearse the rescripted nightmare in an effort to eliminate it. Krakow et al. (2001) found that imagery rehearsal therapy reduced trauma related nightmares and other PTSD symptoms in sexual assault survivors. Other uncontrolled studies have found similar results (e.g., Forbes, Phelps, McHugh, Debenham, Hopewood, & Creamer, 2003).

Imagery rescripting (Smucker, Dancu, Foa & Niedere, 1995) has individuals modify trauma-relevant images and beliefs, particularly those centered around helplessness and lack of power. Individuals are encouraged to substitute mastery imagery for other images in which they perceive themselves as helpless or powerless. Recently Smucker, Grunert, and Weis (2003) suggested that imagery rescripting be used with exposure-based models when nonfear-based emotions are linked to the traumatic experiences (e.g., guilt; Welch & Rothbaum, 2007).

A well-established psychophysiological treatment, biofeedback, involves using a computer to provide feedback to individuals about physiological processes normally outside awareness (e.g., respiration, heart rate, body temperature). The goal of biofeedback is to assist individuals in learning to control and regulate these processes in order to reduce physiological arousal. Most investigations of biofeedback with PTSD have used it in conjunction with other treatment modalities. In addition, most studies of biofeedback with PTSD-diagnosed individuals are poorly controlled and are narrowly

focused (i.e., measure global symptom reduction or one symptom cluster, e.g., Criterion B). Therefore, at present, it is difficult to ascertain whether biofeedback is an effective treatment for PTSD.

Acceptance and commitment therapy (ACT; Hayes, Strosahl, & Wilson, 1999) employs acceptance and mindfulness techniques combined with behavior change strategies to increase psychological flexibility and decrease experiential avoidance. ACT de-emphasizes symptom reduction and attempts to foster a whole integrated approach to the experience of the trauma and bring it in line with the individual's perception of him- or herself. ACT's primary goal is to help patients become more accepting of and willing to experience emotional distress, as opposed to changing thoughts and emotions, as is the focus of traditional cognitive therapies. Orsillo and Batten (2005) suggest that ACT may be a useful alternative to exposure therapy for clients or therapists who are reluctant to employ flooding or systematic desensitization methods. ACT has been utilized as a treatment approach for a number of disorders; however, controlled research studies in PTSD have yet to be conducted. Therefore, it is not clear whether claims that ACT can serve as a useful adjunct or alternative to exposure-based treatments for PTSD are warranted.

Marital and family therapy is often used as an adjunct to traditional PTSD treatment because of the significant effects that trauma exposure and PTSD can have on family relationships. When the need for marital and family therapy is identified, it is recommended that it be conducted concurrently with or following individual treatment for PTSD (Foa et al., 2000). The primary goals in marital and family therapy are to reduce conflict and to increase communication (Foa et al., 2000), and these can be accomplished through the use of a variety of techniques. Glynn and colleagues (1999) conducted the only RCT for behavioral family therapy for PTSD and found that the addition of behavioral family therapy to exposure therapy did not result in further symptomatic improvement. However, preliminary work by Monson, Schnurr, Stevens, and Guthrie (2004) on the application of a 15-session cognitive behavioral couples therapy for post-traumatic stress disorder that was recently developed has produced encouraging results. Cognitive-behavioral couples therapy aims to decrease individual PTSD symptoms and improve relationship functioning, and its efficacy is currently being evaluated in an ongoing clinical trial sponsored by National Institute of Mental Health and conducted by Monson and colleagues (NCT00669981).

Summary and Future Directions for Treatment Research

Research indicates that psychotherapeutic and psychopharmacological treatments are generally effective for patients with PTSD, particularly for civilian populations. Although fewer treatment studies have been conducted with veteran populations, the studies currently in publication suggest promising results. Treatment responders to evidence-based therapies tend to maintain symptom reduction at follow-up; however, as many as half of study participants still meet PTSD diagnostic criteria post-treatment (Bradley, Greene, Russ, Dutra, & Westen, 2005). In addition, some PTSD symptoms (e.g., emotional numbing) are more resistant to treatment than others and may require alternative treatment modalities.

As returning veterans from Iraq and Afghanistan bring to our attention the significant psychological, emotional, and financial costs associated with PTSD, increased attention and resources will likely be made available to advance research on effective treatments. Evaluating the evidence for evidence-based treatments for PTSD and training additional treatment providers may lead to the development of new and effective treatments, thereby increasing the number of future evidence-based therapies for PTSD and related problems. Future studies should focus on the development of novel effective treatments, as well as how to improve the standard of care using existing treatments to facilitate greater treatment responsiveness and generalize findings to a wider variety of trauma-exposed individuals.

PRACTITIONER NETWORK REFERRALS

It is important for clinicians to have multiple resources patients when treating individuals diagnosed with PTSD, because proper assessment and treatment can be very specialized. While the Internet is replete with information about trauma and PTSD, it is often difficult for clinicians to sift through the voluminous information available to determine the source accuracy or validity of this information. We provide here the names of several electronic sites where readers can obtain basic clinical information, handouts for patients, and referral sources. This list does not represent an exhaustive list but should be considered a reliable starting point for informative purposes, as the resources listed were obtained from empirically validated online sources and have been vetted by experts in the field of traumatic stress.

The International Society for Traumatic Stress Studies is an international multidisciplinary professional membership organization that promotes the advancement and exchange of knowledge about trauma. The society's Web site (<http://www.istss.org>) provides excellent information and resources for the treatment of traumatic stress. The Web site offers information for non-members interested in general information about PTSD and also includes links to the National Center for PTSD, as well as other not-for-profit trauma organizations. Information about the psychometric properties of various assessment instruments commonly used in PTSD assessments is provided, along with an index of relevant articles. Members have access to a members-only Web site that provides access to the organization's publications (e.g., *Journal of Traumatic Stress*) and a Listserv of trauma clinicians that allows members to directly contact each other.

The National Center for PTSD maintains a public-access Web site that can be accessed at <http://www.ncptsd.org>. The National Center was created as an information clearinghouse by the U.S. Department of Veteran Affairs and maintains information for clinicians treating both veteran and nonveteran populations. PTSD fact sheets for clinicians, information for patients, and resources for family members are available via the Web site. Links to articles about psychological assessment for PTSD and where to purchase or download various psychological instruments are also available. The center's Web site maintains a link to an electronic index of trauma-related articles in the public domain (PILOTS).

Another important resource for clinicians working with individuals with PTSD is an established practitioner network for treatment referrals. The Association of Behavioral and Cognitive Therapies is a professional organization of practitioners engaged in the practice of empirically validated therapies and is a good resource for locating practitioners skilled in treating PTSD. The association's Web site (<http://www.aabt.org>) provides a link where one can "Find a Therapist" by location and specialty area, including "Posttraumatic Stress Disorder" and "Trauma," among others. The American Psychological Association (<http://www.apa.org>) also has a "Find a Psychologist" link that provides a toll-free number where operators can connect callers to a referral service by state.

Attention-Deficit (Hyperactivity) Disorder

Stephan Bender
Tobias Banaschewski
Franz Resch

Few pathologies have been as controversial as attention-deficit/hyperactivity disorder and attention deficit disorder (ADHD/ADD).¹ Parents of ADHD children have been blamed for not educating their children adequately. The prescription of ADHD medication has been criticized as the chemical tranquilizing of problematic children initiated by the pharmaceutical industry in place of necessary parental attention and guidance. Various theoretical side effects of medication have been highlighted in the popular press. Most authors prefer a dimensional approach and conceive of ADHD rather as an extreme variant of a divergent cognitive style of information processing that is normally distributed in the general population. Such a cognitive information-processing style may be favorable in some circumstances at moderate levels. However, the high intensity of characteristic ADHD symptoms produces considerable individual suffering—especially in school environments—and justifies a categorical diagnosis, which needs an integrated diagnostic and therapeutic approach. Longitudinal studies have shown that untreated ADHD

patients (especially when a comorbid conduct disorder or oppositional defiant behavior are already present) face an increased risk of engaging in criminal behavior or developing an addiction. Secondary social problems that are triggered by impulsive and disorganized behavior are important in this respect.

Molecular and formal genetic studies show the important influence of genetics in ADHD, especially findings with respect to an involvement of the dopaminergic system have been replicated. Neuropsychological studies show a limited specificity, but they demonstrate how executive control is impaired in ADHD. Periodic shifts in the attention level might play a role in ADHD pathophysiology. In many patients, cognitive symptoms alone cannot account for the symptoms; rather, motivation has to be taken into account. Also, the ability of the motor system to suppress certain types of excitation (inhibitory function) might be reduced in ADHD children, leading to behavioral hyperactivity, though no strong association with epileptic disorders has been found. Some studies point to the influence of a delayed or altered maturation, as some ADHD symptoms resemble the normal behavior of younger children. Stimulant medication has proved to normalize many but not all deficits.

1. In the following, we will use the abbreviation ADHD to refer to all *DSM-IV* subtypes of ADD (hyperactive-impulsive, inattentive, and combined subtype), if not otherwise specified.

A diagnostic challenge is provided by the fact that adverse life events and emotional problems might provoke symptoms similar to those of the described biological vulnerability. However, depending on the evolution of the symptoms, in these cases, therapy focused on coping with emotional problems may be preferred by many patients and parents over medication.

We will begin this chapter with an overview of standardized diagnostic procedures (interviews, questionnaires). We will discuss which pathologies and educational problems should be excluded in the diagnostic process and addressed specifically. Moreover, we will present different components and modules of a multidimensional therapeutic approach. Depending on the individual characteristics of each patient, the importance of these components can vary considerably. We give a state-of-the-art overview about new developments with respect to extended-release formulae of stimulants and non-stimulant medication.

FROM CONCEPTS AND THEORY TO CLINICAL PRACTICE

On a scientific basis, there is now strong evidence that ADHD is an extreme form of a highly heritable information-processing style in which many genes with small effect sizes are involved, which, in its extreme phenotypes, can lead to tremendous suffering and to a bad long-term prognosis with respect to professional and personal achievements when not adequately treated. Brain maturation and environmental factors that favor the development of a good cognitive, affective, and impulse control seem to modulate the genetic and temperamental disposition. A multimodal integrative therapeutic approach is recommended, and a good differential diagnosis has to be established to separate children with emotional problems, family conflicts, attachment problems, and social/conduct disorders, as well as children who have experienced neglect or deprivation, from mainly genetically determined forms of ADHD in order to choose the most appropriate therapeutic approach dealing with the actual underlying causes (though sometimes symptomatic approaches may be helpful to support a causal therapy).

Historical Development of Diagnostic Categories

Historically, there were early descriptions of children who showed abundant motor activity. For example, as

early as 1871, Maudsley wrote about an 8-year-old girl with epilepsy. An organic deficit in the brain was assumed to produce a combination of hyperactivity, attention deficits, and behavioral problems (Still, 1902). These were also found in mentally retarded and autistic children.

Indeed, ADHD symptoms resemble a mild form of brain injury to the frontal lobe in adults. Thus initially, attention deficits, impulsivity, and hyperactive behavior were explained as a result of a “minimal cerebral dysfunction.” However, studies revealed that neuronal plasticity in children is higher than in adults and that frontal lobe damage in children does not cause characteristic ADHD symptoms in most children (Halperin & Schulz, 2006). Instead of early (pre-)frontal lesions being the cause of ADHD, a delayed or impaired (pre-) frontal cortex maturation could impair a compensation and executive top-down control of hyperactive and inattentive behavior arising from subcortical structures or a general brain immaturity.

Thus in the *ICD-9* (World Health Organization, 1978) and the *DSM-III* (American Psychiatric Association, 1980) a “hyperkinetic syndrome” with disturbed attention and concentration” and an “attention deficit disorder” were introduced, respectively. The latter could but did not need to be combined with motor hyperactivity. This acknowledged that children with normal intelligence without any known birth complications or other damaging influences to the brain could show ADHD symptoms. In the *DSM-IV-TR* (American Psychiatric Association, 2000) three subgroups are differentiated:

- (1) ADHD, combined type: at least six of nine symptoms of each of the inattentive and the hyperactive/impulsive symptom clusters have to persist over 6 months.
- (2) ADHD, predominantly inattentive type: only six of nine symptoms of the inattentive cluster are met.
- (3) ADHD, predominantly hyperactive/impulsive type: only six of nine symptoms of the hyperactive/impulsive clusters are met.

CORE SYMPTOMS OF ADHD/ADD

Inattention Cluster

- Many ADHD children have difficulties paying attention to motivationally unattractive, monotonous tasks or focusing on play activities.
- The child is not attentive to details or makes many simple (“careless”) errors.

- The child avoids and/or dislikes activities requiring sustained attention (such as homework), maybe because of repeated negative results or an aversion to activities with delayed rewards.
- ADHD children have difficulties organizing complex tasks or activities step by step.
- They do not seem to listen to orders given by adults (no primarily oppositional defiant behavior).
- They do not complete tasks such as homework, chores, or duties in the workplace.
- They are easily distracted by external stimuli.
- They often forget things in daily activities and lose things needed for tasks and activities (pencils, toys, books, or tools).

Some of these symptoms may be causally linked (e.g., children may not be able to complete their homework because they are easily distracted), however, such causal links have yet to be firmly established by empirical data and may vary between individual cases.

Impulsivity Cluster

- The child blurts out an answer before the question has been finished.
- They often have difficulty waiting until it is their turn.
- They interrupt others when they are playing or talking (e.g., butting into a conversation when the someone is talking on the phone).

Abundant Motor Activity (Hyperkinetic Behavior)

- The child is constantly moving his or her hands or feet or squirming in his or her seat.
- He or she often stands up in class or other situations when inappropriate.
- He or she often runs about or climbs when it is not appropriate (in adolescents or in adults this can be limited to a feeling of restlessness).
- The child has trouble playing and enjoying quiet games and leisure activities.
- The child often talks excessively.

The symptoms have to prevail for at least 6 months to an extent that they become disruptive and inappropriate for the developmental level.

Please note that these symptoms should be found in two or more contexts, (e.g., at home, at school, with friends). Thus, situational reactive problems should be

excluded. This does not mean that there will not be situations demanding more sustained attention, where the problems of children with ADHD will be much more evident. However, contextual variables (who else is present, etc.) should not determine whether ADHD symptoms are present or not. Symptoms should be present before the age of 7 (as in many genetic disorders, though others show a late disease onset, such as Huntington's disease).

The severity of the symptoms must lead to clinically relevant impairments of social functioning at school or work. This criterion emphasizes the difference between a simple creative and spontaneous cognitive style and a disorder needing treatment to prevent secondary problems. However, the involvement of many genes and clinical data suggest that a dimensional approach assuming continuous quantitative ADHD traits that are rather normally distributed in the population should complement a categorical clinical approach (full ADHD is either present or absent) in order to adjust therapeutic approaches to the level of severity of ADHD symptoms.

The question of whether the impairment criterion makes the diagnosis of ADHD culture dependent is controversial: people might argue that in a different environment, some children might not even need treatment but would be well adapted and that the primary task should be to change the environment to foster the child's development. The many positive aspects of ADHD, such as the child's liveliness, creativeness, and spontaneity, can and should be regarded as a gift. In this way, ADHD can be understood as an "anachronistic" cognitive style that would be well adapted in the "jungle" but not in our society (Arcos-Burgos & Acosta, 2007). When one is hunting, it can be useful to be able to attend to many things at the same time (e.g., when there is suddenly a sound of an animal). However, even in the jungle one sometimes has to hold still in the presence of an animal for a long time, and studies show that the transcultural prevalence of ADHD is quite stable, depending on the method of assessment.

Regardless, it is impossible (or not even desirable) to radically change the child's environment and society, in most of the cases, because children love their parents and should not be separated from them (unless there are special circumstances), and there are simply some requirements that children have to fulfill. An ADHD diagnosis should be determined when ADHD symptoms prevent the child from accomplishing developmental tasks.

Of course, for the diagnosis of ADHD, the symptoms must not be part of a pervasive developmental disorder, schizophrenia, or any other psychotic disorder.

They must not be better explained as part of another mental disorder.

The *ICD-10* uses the concept of hyperkinetic conduct disorder (conduct disorder based on conflicts due to ADHD), which is regarded as a separate entity with respect to a simple uncomplicated ADHD. This means that in *some but not all* children with ADHD symptoms, a conduct disorder or oppositional defiant disorder can develop when, as a consequence of ADHD symptoms, secondary problems and conflicts in the family arise. This could be the case especially for children with high impulsivity when they are confronted with environmental stressors, such as a parenting style that does not compensate for impulsive outbursts. ADHD with a comorbid conduct disorder may represent a separate diagnostic group with an underlying pathophysiology different from that of simple, uncomplicated ADHD (Albrecht, Banaschewski, Brandeis, Heinrich, & Rothenberger, 2005; Banaschewski, Brandeis, Heinrich, Albrecht, Brunner, & Rothenberger, 2003; Zhou et al. 2008). Conduct problems themselves can negatively influence a process of internalizing good relationships to control the child's emotions and allow him or her to gain a positive self-concept. This can lead to a further impairment of self-regulation, social behavior problems leading to criminal behavior, and the development of an antisocial personality disorder and substance abuse.

Wender (1995) includes rapidly changing affective states and problems in emotional self-control as symptoms of ADHD in adult subjects. This opens up the important possibility that ADHD may represent a risk factor for the development of emotionally instable personality disorder (borderline and impulsive subtypes).

DIAGNOSTICS: TESTS, METHODS, AND INSTRUMENTS

A reliable diagnosis should be established by a psychologist, psychotherapist, or psychiatrist who specializes in children (or on adults, when the patient is an adult). However, interdisciplinary networks with educational settings such as a kindergarten or elementary school and first-line medical institutions such as general doctors and pediatricians are necessary. Good cooperation between parents, teachers, social workers, psychologists, pediatricians, and psychiatrists is needed for early recognition so that interventions can be conducted in a timely manner. Therefore, psychoeducation of teachers and physicians as well as the general public is an essential task.

The most common rating scales for parents and teachers are the revised Conners' Parent Rating Scale

and the revised Conners' Teacher Rating Scale (Conners, Sitarenios, Parker, & Epstein, 1998a, 1998b). They are well established in the standardized diagnostic procedure for ADHD as well as for the monitoring of symptoms during treatment (Conners, 1998, 1999). *DSM-IV* criteria can be assessed in a standardized way, for example, by the SNAP-IV (Swanson, Posner, Fusella, Wadell, Sommer, & Fan, 2001). The ADHD Rating Scale IV (Zhang, Faries, Vowles, & Michelson, 2005) can also be applied by clinicians to assess symptom severity.

Despite some weaknesses (Rowe & Rowe, 1997), abbreviated versions of the Conners rating scales allow us to assess the short-term effectiveness of stimulant medication in terms of the stimulants' rapid action onset and short half-life. An individual double-blind trial with encapsulated placebo or stimulant medication and behavioral assessments by teachers and parents can later be compared to the effects of verum therapy: do decreases of ADHD symptoms covary with verum stimulant medication? This distinction seems important, as there are at least some conditioned or placebo effects in ADHD when part of the stimulant medication being used is exchanged and continued by placebo (Sandler & Bodfish, 2008).

Though there are practical limitations, teacher and parent ratings should be completed through behavior observation. For some children, this is difficult, because they will not demonstrate hyperactive or inattentive behavior in the dyadic examination situation. Though the persistence of ADHD symptoms in different situations is a very important criterion, it is not always possible to objectify ADHD symptoms by observation. However, because there is considerable variation in what parents and teachers consider normal (Karlovic, Martinac, Gale, Markic, & Marcinko, 2005) this is an important diagnostic part, especially when home- or in-patient treatment is possible. Self-reports may not be a reliable measurement (Curko Kera, Marks, Berwid, Santra, & Halperin, 2004).

In order to examine whether the level of difficulty of the demands at school is appropriate for the child, a full-scale intelligence test should be performed. Due to high comorbidities, learning disorders (dyslexia and dyscalculia) should be excluded through additional reading, writing, and math tests. The exploration of the family situation and the relationship between the child and his or her parents should complete the diagnostic assessment.

Alternative explanations for hyperactive/inattentive behavior (any kind of problem or conflict that can be solved) must be discarded. A child afraid of being repeatedly insulted and attacked by a group of children

at school might not be able to concentrate because of worries about what may happen during the next break. The differential diagnosis thus includes, among others, emotional problems, post-traumatic hyperactivity, family problems (conflicts, inconsistent education), deprivation, attachment problems, oppositional defiant disorder, conduct disorder, low intelligence and inappropriately high demands, boredom due to extremely high intelligence or a maturational lag (immature children and younger children move more and concentrate less). Some of these conditions can occur together with ADHD (see discussion of comorbidity below), leading to mixed clinical pictures. In these cases a good diagnosis of all comorbid conditions can be crucial to the choice of the most appropriate therapeutic approach. Bipolar disorder has recently become another important differential diagnosis (Adler, Delbello, Mills, Schmithorst, Holland, & Strakowski, 2005). Symptoms of child bipolar disorder are postulated to differ from those of adult bipolar disorder (L. Kent & Craddock, 2003; Kyte, Carlson, & Goodyer, 2006), and recently marked increases in the diagnosis of bipolar disorder have been shown (Moreno, Laje, Blanco, Jiang, Schmidt, & Olfson, 2007). The decisive question seems to be whether mood changes (also mixed mood states) can be explained in ADHD, which involves impulsiveness and difficulties with emotional control; whether certain mood changes are assumed to be normal in children; and when the line separating ADHD and bipolar disorder is crossed. Further research will help to clarify this issue.

A retrospective assessment may be possible in adults with the Wender Utah Rating Scale (Mackin & Horner, 2005; Stein, Sandoval, Szumowski, Roizen, Reinecke, Blondis, & Klein, 1995; Ward, Wender, & Reimherr, 1993; Wierzbicki, 2005), which has been translated into many languages (Bayle, Krebs, Martin, Bouvard, & Wender, 2003; Fossati, Di Ceglie, Acquarini, Donati, Donini, Novella, & Maffei, 2001; K. H. Krause, 2003; Oncu, Olmez, & Senturk, 2005; Retz-Junginger, Retz, Blocher, Weijers, Trott, Wender, Rossler, 2002; Rosler et al., 2004), though some healthy subjects may be misclassified (McCann, Scheele, Ward, & Roy-Byrne, 2000). The retrospective nature of the instrument has to be taken into account, thus supplemental information (e.g., from the clinical patient history and/or an examination of the patient) could be desirable.

At the moment, the diagnosis would not be based on further neuropsychological testing (e.g., computerized continuous performance test plus actigraphic registrations), which can only serve to complete the clinical picture. However, future developments may point in this direction in the search for objective diagnostic markers.

EPIDEMIOLOGY AND CLINICAL COURSE

Prevalence

Seven percent prevalence of ADHD has been estimated in the United States (Bloom & Cohen, 2007; Froehlich, Lanphear, Epstein, Barbaresi, Katusic, & Kahn, 2007). Similar rates have been found in many international studies, depending on the applied criteria and report sources (Ford, Goodman, & Meltzer, 2003; Michanie, Kunst, Margulies, & Yakhkind, 2007; Petersen, Bilenberg, Hoerder, & Gillberg, 2006; Pineda, Lopera, Palacio, Ramirez, & Henao, 2003). Worldwide pooled prevalence has been estimated to be 5% (Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007), indicating that most variability across studies is introduced by methodological issues, while international ADHD prevalence is rather constant. However, increased school pressure may lead to more frequent ADHD diagnosis in particular areas (Schneider & Eisenberg, 2006). Adult ADHD is less common than ADHD during childhood and accounts for about 4% of the population (Kessler et al., 2006). Girls are less likely to be identified because they show fewer hyperactive symptoms (Froehlich et al., 2007); however, boys are more likely to develop ADHD with an estimated ratio ranging from 2:1 to 4:1.

Comorbidities

Common comorbidities in ADHD children are conduct disorder (CD) and oppositional defiant disorder (ODD; Spencer, 2006; Pliszka, 2003; van Lier, van der Ende, Koot, & Verhulst, 2007). There has been some discussion as to whether ADHD shares most of its genetic liability with conduct disorder, oppositional defiant disorder, and executive function deficits (Coolidge, Thede, & Young, 2000). Many studies indicate that ADHD accompanied by ODD/CD represents a different entity (Stevenson, Asherson, Hay, Levy, Swanson, Thapar, & Willcutt, 2005). Some overlaps between ADHD and ODD/CD may exist with respect to impulsivity. In some patients, social problems in children with ADHD may indicate pervasive developmental disorders (Nijmeijer, Minderaa, Buitelaar, Mulligan, Hartman, & Hoekstra, 2008), in which hyperactive and inattentive symptoms are common.

Mood disorders and anxiety disorders are also commonly seen comorbidities in ADHD (Schatz & Rostain, 2006; Spencer, 2006). There have been reports that ADHD plus anxiety may differ from ADHD plus ODD/CD (Jensen et al., 2001), as anxiety may reduce impulsivity and response inhibition deficits but make working memory deficits worse (Schatz & Rostain, 2006).

Dyslexia (Duncan, Rumsey, Wilkniss, Denckla, Hamburger, & Odou-Potkin, 1994) is also frequently observed in ADHD children, as impaired attention and auditory working memory make spelling more difficult). Shared genetic influences with inattention, but not hyperactivity/impulsivity, have been described (Willcutt, Pennington, Olson, & DeFries, 2007). Sleep disorders (Efron & Pearl, 2003; van der Heijden, Smits, & Gunning, 2006) often occur, and some authors believe that biological rhythms, including circadian rhythms, are impaired in ADHD. Elimination disorders (Ishii, Takahashi, Kawamura, & Ohta, 2003) such as primary enuresis nocturna have also been observed as well as mental retardation (Ishii et al., 2003). Enuresis nocturna is related to a delayed or disturbed brain maturation and it is thus plausible that by a delayed maturation of executive control function it is associated with ADHD.

Finally, tic disorder (motor cortex inhibitory deficit; Greimel, Herpertz-Dahlmann, Gunther, Vitt, & Konrad, 2008) and epilepsy (Hermann et al., 2007; McIntyre & Gilby, 2007) may also coexist with ADHD. ADHD plus tic disorder may differ from ADHD without tic disorder with respect to the underlying pathophysiology but does not represent a homogeneous category itself (Rothenberger, Roessner, Banaschewski, & Leckman, 2007). While only a small number of ADHD children suffer from epilepsy, the prevalence of ADHD in epilepsy patients has been found to be considerably greater (31%; Hermann et al., 2007) than in the general population (about 5%).

Untreated ADHD

It is unclear whether ADHD treatment can alter the course of the disease itself. However, treatment can prevent ADHD children from facing secondary problems like failure at school or the development of a conduct disorder. Though the majority of all ADHD subjects (especially those with an uncomplicated ADD) will never show antisocial behaviors, the risk of engaging in adult criminal activities is increased for untreated childhood ADHD patients (Babinski, Hartsough, & Lambert, 1999; Sourander et al., 2006). ADHD is frequently found in prisons (Rasmussen, Almvik, & Levander, 2001). ADHD as well as developmental coordination disorder have been found to be the best predictors for early adult functioning (Rasmussen & Gillberg, 2000).

However, it should be noted that psychiatric disorders in adulthood are more directly related with rule-breaking behavior than with attention deficits (Hofstra, der Ende, & Verhulst, 2002), so that association may be modulated by secondary conflicts due to ADHD or CD/ODD.

ADHD, not stimulant treatment (Mannuzza, Klein, Truong, Moulton, Roizen, Howell, & Castellanos, 2008), may increase the risk of substance abuse (Fischer & Barkley, 2003), though higher rates have also been described for treated subjects (Lambert & Hartsough, 1998). ADHD during adolescence may be a better predictor for substance abuse than ADHD in younger subjects (Molina, Pelham, Gnagy, Thompson, & Marshal, 2007).

The estimates for a persistence of ADHD into adulthood range between about 5% (Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1993, 1998) and 60% (Barkley, Fischer, Smallish, & Fletcher, 2002; Borland & Heckman, 1976; Gittelman, Mannuzza, Shenker, & Bonagura, 1985; Schmidt, Esser, & Moll, 1991; Yan, 1996) depending on the applied criteria, because symptoms seem to change in many domains during maturation. Hyperactive symptoms often are greatly reduced, while inattention and sometimes impulsivity tend to persist.

Prognosis of Treatment

Fifty to 80% of subjects respond to stimulant medication treatment, with most estimates around 70% (Spencer, Biederman, Wilens, Harding, O'Donnell, & Griffin, 1996). A normalization (as most minor difficulties remain) of parent and teacher ratings is achieved in 40%–70% of the cases (Banaschewski et al., 2008b). The effect size (standardized mean difference) at which the response to methylphenidate (MPH) exceeds the response to placebo has been found to be about 1, which means one pooled standard deviation over both the experimental and the control group (Banaschewski et al., 2008a). This is a relatively strong effect compared to other types of psychotropic medication. However, adherence to prescribed medication can represent a problem and be below 30% (Weiss, Gadow, & Wasdell, 2006). Comorbid anxiety disorders have been related to a poorer outcome (Garland, 1998), but this was not confirmed in the Multimodal Treatment Study of Children with ADHD (MTA Cooperative Group, 1999b). Positive predictors for a response to stimulant treatment are higher ADHD symptom scores and younger age (Eggers, Fegert, & Resch, 2004).

Multimodal treatment is slightly superior to the medication-alone approach under specific conditions or when symptoms other than ADHD core symptoms are present (MTA Cooperative Group 1999a, 1999b). Multimodal and psychotherapeutic interventions are especially warranted when patients refuse to use medication (or their parents do not give their permission for medication to be used), for non-responders, and for

patients with comorbidities and/or (secondary) social problems. Whether recent specific neurofeedback approaches will improve the overall response rate has not been shown yet.

Taking all therapeutic options into account, in most cases ADHD symptoms can be well treated, if good compliance of the parents and the patient to medication and/or therapeutic/educational interventions can be achieved. Despite widespread concern, no overprescription of stimulants in the general population could be shown for a population-based sample in four U.S. communities; in contrast, in many patients they were not used (Jensen et al., 1999). However, in other populations results may differ. It is now known that stimulants focus attention in both ADHD patients and normal subjects (Arnsten, 2006); however, misuse or psychoenhancement by normal subjects to increase performance has been strongly criticized.

Neuropsychological Profiles of ADHD Deficits

Neuropsychological investigations often show moderate effect sizes with respect to differences between healthy subjects and ADHD patients, but there have been difficulties establishing a reliable specific pattern of executive function impairments in ADHD compared to other patient groups. Generally, the dual pathway model is supported (Sonuga-Barke, 2002, 2003). In this model, there are problems in executive control (working memory, sustained attention, selective attention, inhibitory control) that may be related to prefrontal cortex and/or striatal dysfunction (related to the mesocortical and the mesostriatal dopaminergic systems).

Additionally, a motivational disturbance would result in an aversion to delayed rewards and a preference of frequent and immediate rewards (R. M. Roth & Saykin, 2004). One hypothesis is that delays have to be filled by ADHD patients with other stimuli. This can lead to attentional problems as a secondary effect. This delay aversion has been postulated to be related to the mesolimbic dopaminergic system.

With respect to specific executive function deficits, one of the most examined subjects has been the continuous performance test, where rare targets have to be detected over a long period of time (sustained attention). A subject of interest has been whether ADHD patients make more commission errors (false alarms). However, results have not been entirely conclusive in terms of whether commission errors are generally more common for ADHD than omission errors. Deficits in the

continuous performance test appear to be rather unspecific for various psychiatric disorders.

There has been an extensive search for a specific neuropsychological ADHD profile: deficits have been found in the Stroop effect (Corbett & Stanczak, 1999; Lansbergen, Kenemans, & van Engeland, 2007); the variability of reaction times (Rucklidge & Tannock, 2002); response inhibition (R. M. Roth & Saykin, 2004); temporal processing (Barkley, Murphy, & Bush, 2001; R. M. Roth & Saykin, 2004); working memory, affect regulation, arousal, and speech internalization (Barkley, 1997); motor inhibition (Carr, Nigg, & Henderson 2006); motor response organization (Himelstein & Halperin, 2000); movement variability (Kalff et al., 2003); and strategy generation and cognitive flexibility (Chan, Guo, Zou, Li, Hu, Yang, 2006). However, overall full-scale IQ may be related to ADHD, as these more specific measures (Frazier, Demaree, & Youngstrom, 2004; Hinshaw, Carte, Fan, Jassy, & Owens, 2007). The neuropsychological profiles of the different ADHD subtypes have not been found to differ from each other or other psychiatric diseases (Geurts, Verte, Oosterlaan, Roeyers, & Sergeant, 2005). In general, a wide range of executive functions seems impaired in ADHD, particularly memory, attention, inhibition, and motor coordination, in contrast to simple reaction time duration. Impaired executive function in ADHD could also indicate limited abilities to compensate for another more specific ADHD deficit.

Complex multilevel models have been suggested (Nigg, 2005) to provide integrative theories for deficits in various domains. We encourage our readers to follow the converging findings throughout this chapter from theoretical considerations over comorbidity and neuropsychology to neuroimaging and genetics.

NEUROPHYSIOLOGICAL, BIOPSYCHOLOGICAL, AND PSYCHOPHYSIOLOGICAL UNDERPINNINGS

Catecholamines (dopamine and norepinephrine) are two neuromodulators involved in vigilance, attentional control, and motivation. At least two of three dopaminergic systems (mesolimbic and mesocortical) seem to be involved in ADHD pathophysiology (Sonuga-Barke, 2002, 2003; Thorell, 2007). Mesolimbic connections and dopamine release in the nucleus accumbens are related to motivational deficits (Sagvolden, Johansen, Aase, & Russell, 2005). Executive control deficits have been

related to the mesocortical system (Sagvolden et al., 2005; Viggiano, Vallone, Ruocco, & Sadile, 2003). However, general vigilance mediated mainly by norepinephrine could play an important role as well (Huang-Pollock, Nigg, & Halperin, 2006).

Dopaminergic Function

The main origin of dopaminergic neurons is the ventral tegmentum and the basal ganglia (substantia nigra). From the ventral tegmentum, the fibers of dopaminergic neurons project to the nucleus accumbens (mesolimbic system), but also to the prefrontal cortex (mesocortical system). From the substantia nigra, dopaminergic neurons project to the striatum (mesostriatal system). While the mesocortical system subserves attention and executive functioning in the prefrontal cortex, the mesolimbic system is related to motivation, novelty seeking, and learning by conditioning (reward system). The mesostriatal system is involved in movement initiation (disturbed in Parkinson's disease) and sustained attention (Sagvolden et al., 2005; van den Heuvel & Pasterkamp, 2008).

Both hyper- and hypodopaminergic animals show hyperactive motor behavior (Gainetdinov, Jones, & Caron, 1999; Ohno, 2003; Viggiano et al., 2003). Dopamine plays an important role in the anterior attention system (prefrontal cortex and cingulum), which is related to cognitive flexibility, response monitoring, and inhibition. Other dopaminergic neurons also project to temporal and parietal cortical association areas, where the posterior attention system (especially right parietal cortex) is located (Huang-Pollock et al., 2006). It plays a role, for example, in visual attention.

Norepinephrine

In contrast, norepinephrine receptors are found in primary visual, auditory, somatosensory, and also motor regions. Norepinephrine is produced in the locus coeruleus and the lateral tegmentum. They subserve the subject's vigilance and show reduced activity during drowsiness and sleep (Kalia, 2006). Very roughly speaking, norepinephrine is thought to be implicated in overall vigilance, while dopamine subserves focused and sustained attention. Norepinephrine was also recently found to be phasically regulated according to task requirements (Aston-Jones & Cohen, 2005). The catecholaminergic systems are strongly involved in the fronto-striatal circuits (lateral prefrontal cortex, dorsal anterior cingulate cortex, caudate, and putamen), which

have been proposed to be the main cerebral correlate of ADHD dysfunction (Bush, Valera, & Seidman, 2005).

Transmitter Metabolism

Studies looking at metabolites of catecholamines in the cerebrospinal fluid have yielded no consistent results. There have been reports of diminished homovanillic acid (Castellanos, Elia, et al., 1994; Castellanos, Elia, et al., 1996; Shaywitz, Cohen, & Bowers, 1977), a main metabolite of dopamine. However, findings have not been consistent in every study (Cohen, Caparulo, Shaywitz, Bowers, 1977; Reimherr, Wender, Ebert, & Wood, 1984); age-related maturation could play an important role as well as the response to methylphenidate. Diminished 3-methoxy-4-hydroxyphenylglycole, a main metabolite of norepinephrine, and other catecholaminergic metabolites in the urine (Hanna, Ornitz, & Hariharan, 1996; Oades, 2002), has also been observed, although there are contradictory findings here as well (Baker, Bornstein, Douglass, Van Muyden, Ashton, & Bazylewich, 1993). Diminished 5-hydroxyindoleacetate (5-HIAA) could correlate with aggressive rather than impulsive behavior (Kruesi, Rapoport, Hamburger, Hibbs, Potter, Lenane, & Brown, 1990; Soderstrom, Blennow, Manhem, & Forsman, 2001; Soderstrom, Blennow, Sjodin, & Forsman, 2003). In individuals with ADHD, a rather a low ratio of homovanillic acid to 5-HIAA was found (Oades, 2002).

Non-Invasive Imaging of Transmitter Systems

PET (positron emission tomography) findings are also not without contradictions but show a more consistent pattern (Diaz-Heijtjz, Mulas, & Forssberg, 2006): While in adults a prefrontal dopaminergic deficit has been described (Ernst, Zametkin, Matochik, Jons, & Cohen, 1998), adolescents may show dopaminergic abnormalities in the basal ganglia (Forssberg, Fernell, Waters, Waters, & Tedroff, 2006; Jucaite, Fernell, Halldin, Forssberg, & Farde, 2005; Ludolph et al., 2008), which may still be present in adulthood (J. Krause, 2008; Spencer et al., 2007), though the findings in adults are highly controversial (Volkow et al., 2007). Developmental aspects have to be taken into consideration. High dopamine receptor availability (empty receptors) together with neonatal low cerebral blood flow (e.g., due to ischemia) represent a risk factor for the development of ADHD in adulthood (Lou, Rosa, Pryds, Karrebaek, Lunding, Cumming, & Gjedde, 2004).

With respect to functional task-related dopaminergic activity, methylphenidate has been found to increase the dopaminergic response to weak stimuli (Volkow, Wang, Fowler, & Ding, 2005). SPECT (single-photon emission computerized tomography) has revealed a decreased prefrontal cortex perfusion in ADHD (Amen & Carmichael, 1997).

Brain Morphology/Anatomy

Volume reductions in ADHD have been described for the total cortical volume, especially for the (pre-) frontal cortex (Carmona et al., 2005; Castellanos, Giedd, et al., 1996; Kates et al., 2002; Seidman et al., 2006); the basal ganglia, often with altered asymmetry (Castellanos, Giedd, et al., 1994; Castellanos et al., 2002; Schrimsher, Billingsley, Jackson, & Moore, 2002; Uhlir, Paclt, Vaneckova, Morcinek, Seidel, Krasensky, & Danes, 2007); the anterior cingulate cortex (Seidman et al., 2006; Semrud-Clikeman, Pliszka, Lancaster, & Liotti, 2006); the corpus callosum (Hutchinson, Mathias, & Banich, 2008; Hynd, Semrud-Clikeman, Lorys, Novey, Eliopoulos, & Lyytinen, 1991; Seidman, Valera, & Makris, 2005); and the cerebellum (Berquin, Giedd, Jacobsen, Hamburger, Krain, Rapoport, & Castellanos, 1998; Castellanos et al., 2001; Mackie et al., 2007). Right basal ganglia lesions have been shown to produce deficits in emotion control as well as disinhibition and increased aggression (DeLong, 2002).

Functional Brain Activation in ADHD

Functional imaging studies show inhibition deficits in (pre-)fronto-striatal loops (Booth et al., 2005; Durston, Mulder, Casey, Ziermans, & van Engeland, 2006; Pliszka, Glahn, Semrud-Clikeman, Franklin, Perez, Xiong, & Liotti, 2006; Rubia, Overmeyer, Taylor, Brammer, Williams, Simmons, & Bullmore, 1999; Schulz, Newcorn, Fan, Tang, & Halperin, 2005; Shafritz, Marchione, Gore, Shaywitz, & Shaywitz, 2004; Vaidya, Bunge, Dudukovic, Zalecki, Elliott, & Gabrieli, 2005) though in some studies even a (compensatory?) over-activation measured by functional magnetic resonance imaging was found (Schulz, Fan, Tang, Newcorn, Buchsbaum, Cheung, & Halperin, 2004). Prefrontal dysfunction may also be present during memory tasks (Sheridan, Hinshaw, & D'Esposito, 2007).

A hypoactivation of the anterior cingulate has been found in a Stroop task, when the prepotent response to read a word has to be suppressed and the color of the letters has to be indicated instead (Bush et al., 1999), and during error detection (Rubia, Smith, Brammer,

Toone, & Taylor, 2005). These effects may be partially normalized by methylphenidate (Bush et al., 2008).

Hypoactivation of the superior temporal gyrus in an oddball task has been interpreted as a sign of reduced efficiency of the allocation of attentional resources (Rubia, Smith, Brammer, & Taylor, 2007). Reward processing may be altered in ADHD in the basal ganglia (reduced activation during anticipation) as well as the orbitofrontal cortex (increased activation to gain outcomes) (Strohle et al., 2008). There are also further hints of a rostral prefrontal cortex deficit in ADHD (Dumontheil, Burgess, & Blakemore, 2008).

Apart from executive control and reward processing, motor hyperactivity is a core sign of ADHD. Accordingly, motor and sensory cortex activation (Mostofsky, Rimrodt, Schafer, Boyce, Goldberg, Pekar, & Denckla, 2006; Rubia et al., 1999; Teicher, Anderson, Polcari, Glod, Maas, & Renshaw, 2000) but also spatial memory in the right parietal cortex (Vance, Silk, Casey, Rinehart, Bradshaw, Bellgrove, & Cunningham, 2007) have been found to be altered in ADHD.

Finally, disrupted connections between the prefrontal cortex and amygdala could reflect difficulties in emotion regulation (Plessen et al., 2006).

NEUROPHYSIOLOGY

Resting State

Quantitative EEG (qEEG) points toward a slowing especially in frontal regions (Barry, Clarke, & Johnstone, 2003; El-Sayed, Larsson, Persson, & Rydelius, 2002; Hermens, Soei, Clarke, Kohn, Gordon, & Williams, 2005). However, the sensitivity/specificity of a low beta-to-theta ratio (Coolidge, Starkey, & Cahill, 2007) is limited and this finding has not always been replicated (Bresnahan & Barry, 2002; Swartwood, Swartwood, Lubar, & Timmermann, 2003). There has been much discussion about whether these qEEG findings indicate a maturational delay or a deviant pattern of activation. As slower frequencies represent low arousal in contrast to faster desynchronized frequencies, such a slowing could indicate an under-arousal, which provides the physiological basis for a specific frequency-based neurofeedback (see chapter 29).

The short- and long-term connection pattern has been found to be affected in ADHD, as reflected by complex patterns of coherence differences (Barry, Clarke, McCarthy, Selikowitz, & Johnstone, 2005; Murias, Swanson, & Srinivasan, 2007). EEG coherence indicates the extent to which the signals at two different channels

resemble each other and provide an indicator for the extent of neuronal coupling between both areas.

Task-Related Activation

Deficits have been found at different stages of information processing in ADHD by means of event-related EEG potentials. Most findings were related to attention and response inhibition. Usually rare targets (20%) have to be detected among frequent distractors (80%)—the so-called oddball task. In the Go variant, the target requires a motor response, while in a NoGo task, the motor response to the frequent distractor has to be inhibited when a target occurs.

During early information processing, deficits in orienting and the attentional tuning of sensory processing have been described during the N1 event-related potential component (Banaschewski & Brandeis, 2007). N1 is increased in attended stimuli. The event-related N2-component is increased by response inhibition to NoGo target stimuli. Some studies found an N2 reduction in ADHD as a correlate of reduced inhibitory control (Broyd, Johnstone, Barry, Clarke, McCarthy, Selikowitz, & Lawrence, 2005; Pliszka, Liotti, & Woldorff, 2000). However, this finding could not be replicated by other studies (J.L. Smith, Johnstone, & Barry, 2004; Wiersema, van der Meere, Antrop, & Roeyers, 2006). In contrast, deficits in the anterior cingulate have been described (Fallgatter, Ehlis, Rosler, Strik, Blocher, & Herrmann, 2005; Fallgatter et al., 2004; Reif, Fallgatter, Ehlis, & Lesch, 2004). Disease-related differences in expectation and attention could play a more important role in ADHD than a mere inhibition deficit (Banaschewski, Brandeis, Heinrich, Albrecht, Brunner, & Rothenberger, 2004; Kenemans, Bekker, Lijffijt, Overtom, Jonkman, & Verbaten, 2005).

Low amplitudes in the event-related P300 potential could point to difficulties allocating attentional resources to relevant target stimuli to update the context in working memory (Brandeis et al., 2002; Du et al., 2006; Sawaki & Katayama, 2006; Zillessen, Scheuerpflug, Fallgatter, Strik, & Warnke, 2001). P300 reduction may be normalized by methylphenidate (Seifert, Scheuerpflug, Zillessen, Fallgatter, & Warnke, 2003). However, P300 reductions have been described for many psychiatric disorders (unspecific finding).

Slow Cortical Potentials

When a spontaneous movement is prepared or the subject anticipates a stimulus, so-called slow brain activity develops. The potential, which reflects response prepa-

ration and stimulus anticipation when a subject waits for a target stimulus requiring a fast motor response, has been called contingent negative variation. Contingent negative variation has been found to be reduced in ADHD (Perchet, Revol, Fournieret, Mauguier, & Garcia-Larrea, 2001).

Hints have been found that a low lateralized readiness potential in ADHD indicates reduced focal motor cortex activation and preparation of a movement (Steger, Imhof, Steinhausen, & Brandeis, 2000). The motor system undergoes continued maturation throughout childhood and adolescence. While the posterior attention system may be mature by the age of 6, as indicated by slow cortical potentials related to the anticipation of a stimulus, the potentials related to movement preparation continue to undergo profound changes (Bender, Weisbrod, Bornfleth, Resch, & Oelkers-Ax, 2005): Before the age of 6 the readiness potential is positive, and stable negative values are reached only by puberty, around 12 years of age. A substitution of synapses at the pyramidal cell bodies by axodendritic synapses or changes in the basal ganglia have been suggested. This maturation seems to be specific to the movement preparation stages, as other motor cortex potentials during movement postprocessing follow a different maturational trajectory (Bender, Weisbrod, Resch, & Oelkers-Ax, 2007). In children this movement preparation mainly seems to be related to disinhibition, in which dopamine in the basal ganglia could be implicated (Bender, Basseler, Sebastian, Resch, Kammer, Oelkers-Ax, & Weisbrod, 2005).

The slow potential findings in ADHD provide a physiological basis for the neurofeedback of slow cortical potentials (Drechsler, Straub, Doehnert, Heinrich, Steinhausen, & Brandeis, 2007; Heinrich, Gevensleben, & Strehl, 2007; Leins, Goth, Hinterberger, Klinger, Rumpf, & Strehl, 2007; see also chapter 29).

Potentials Following Response Execution

With respect to response efficacy evaluation, reduced error awareness and higher conflict sensitivity have been found in individuals with ADHD (Albrecht et al., 2008; Burgio-Murphy et al., 2007; Jonkman, van Melis, Kemner, & Markus, 2007; Liotti, Pliszka, Perez, Kothmann, & Woldorff, 2005; van Meel, Heslenfeld, Oosterlaan, & Sergeant, 2007; van Meel, Oosterlaan, Heslenfeld, & Sergeant, 2005; Wiersema, van der Meere, & Roeyers, 2005). This accompanies enhanced late negativity, the so-called postimperative negative variation, in conditions of loss and lack of control (Yordanova, Dumais-Huber, Rothenberger, & Woerner, 1997).

Periodic Changes in Vigilance

Slow periodic changes (<30 s) in vigilance are visible in the activation of a default mode network in the anterior/posterior cingulate: when no controlled task-related activation takes place, the default mode network is activated. Periods with increased inattention could account for ADHD symptoms (Castellanos et al., 2008; Helps, James, Debener, Karl, & Sonuga-Barke, 2008) and lead to an increased variability of behavioral measures such as reaction times (Klein, Wendling, Huettner, Ruder, & Peper, 2006; Rucklidge & Tannock, 2002; Sonuga-Barke & Castellanos, 2007).

Also on a neurophysiological level, increased single-trial variability in P300 amplitudes has been described (Lazzaro, Anderson, Gordon, Clarke, Leong, & Meares, 1997). However, the specificity of this finding is very limited, as it is also present in other disinhibiting disorders and in schizophrenic patients with executive functioning deficits (Bender, Weisbrod, & Resch 2007; Iacono, Carlson, Malone, & McGue, 2002; Kaiser, Roth, Rentrop, Friederich, Bender, & Weisbrod, 2008; A. Roth, Roesch-Ely, Bender, Weisbrod, & Kaiser, 2007).

Cortical Excitability and Connectivity (Transcranial Magnetic Stimulation)

Cortical inhibition deficits can be directly assessed by transcranial magnetic stimulation (Bender, Basseler, et al., 2005). Inhibition deficits in the motor cortex have been described. These may be reversed by methylphenidate intake, though physiological maturation has to be taken into account (Buchmann et al., 2007; Garvey & Mall, 2008; Gilbert, 2006; Gilbert, Bansal, Sethuraman, Sallee, Zhang, Lipps, & Wassermann, 2004; Moll, Heinrich, & Rothenberger, 2003; Moll, Heinrich, Trott, Wirth, & Rothenberger, 2000; Moll, Heinrich, Trott, Wirth, Bock, & Rothenberger, 2001; Ucles, Serrano, & Rosa, 2000). TMS can further be used to assess cortical connectivity, for example, via the corpus callosum (Buchmann, Wolters, Haessler, Bohne, Nordbeck, & Kunesch, 2003; Garvey et al., 2005).

Genetics

High Heritability

Twin studies have yielded high heritability estimates for ADHD (Coolidge et al., 2000; Faraone, Perlis, Doyle, Smoller, Goralnick, Holmgren, & Sklar, 2005; Levy, Hay, McStephen, Wood, & Waldman, 1997; Martin, Scourfield, & McGuffin, 2002; Stevenson, 1992; Willcutt,

Pennington, & DeFries, 2000) comparable to that found in schizophrenia, which is among the highest for psychiatric disorders. These estimates are based on how much more concordant monozygotic twins (50%–80%) are found to be compared to dizygotic twin pairs (about 35%) with respect to ADHD symptoms, leading to heritability estimates of 0.6–0.8. A slight confounder in this method is parental attitudes, which may be different among the parents of monozygotic twins (identical twins) than those of dizygotic twins, whose roles in the family might be distributed more diversely. This could lead to an underestimation of environmental influences. It seems important to note that the subtype of ADHD in one patient does not predict the ADHD subtypes in his or her relatives (Smidt et al., 2003). Heritable risk factors might predispose for different forms of ADHD. It is assumed that many gene polymorphisms have to come together to foster ADHD. This is in agreement with whole genome scans (Arcos-Burgos et al., 2004; Bakker et al., 2003; Fisher et al., 2002; Hebebrand et al., 2006; Loo et al., 2004; Ogdie et al., 2006; Romanos et al., 2008), which did not find single genes explaining large parts of the ADHD risk (Faraone et al., 2007; Mick & Faraone, 2008).

Candidate gene studies so far have mainly targeted genes involved in the dopaminergic system: DAT 1, DRD4, DRD5, DRD2, and DBH, but also 5HTR1B. In general, for some of the key genes significant results, but with very small odds ratios have been found. In general, there are a couple of types of genes directly involved in dopaminergic transmission: genes that account for dopamine synthesis/degradation (availability of the transmitter), genes that regulate the synaptic density and the integrity of neurons, and genes that regulate the vesicle transport and transmitter release, the dopamine receptors and the dopamine transporter.

DAT1 Gene

The dopamine transporter (DAT) removes dopamine from the synaptic cleft and thus reduces its effects (Swanson et al., 2000). DAT “knockout” mice (in which the DAT gene has been “inactivated”) show hyperactive behavior and an inhibition deficit (Gainetdinov, Wetsel, Jones, Levin, Jaber, & Caron, 1999). Please note that in this knockout model, developmental effects (possible role of the dopamine level in fetal and postnatal neurodevelopment) and current state effects are confounded. Stimulants such as methylphenidate block the dopamine transporter as one mechanism of action. The treatment of the knockout mice could alleviate their symptoms (Gainetdinov, Wetsel, et al., 1999). In these knockout

mice an increase in extracellular dopamine levels was seen only transiently, while afterward dopaminergic down-regulation led to a hypo-dopaminergic state (Faraone et al., 2005; Gainetdinov, Jones, & Caron, 1999).

Polymorphisms in genes can consist of short repetitive DNA sequences (variable number tandem repeats). The 10-repeat DAT-1 allele produces a more effective DAT (Swanson et al., 2000). This allele was found to be a risk factor for ADHD (Brookes, Neale, Sugden, Khan, Asherson, & D'Souza, 2007; Comings, 2001; Curran et al., 2001; Durston, Fossella, Mulder, Casey, Ziermans, Vessaz, & Van Engeland, 2008; Feng, Wigg, et al., 2005; Gilbert et al., 2006; Lin & Uhl, 2003; Mitchell et al., 2000; Qian, Wang, Zhou, Yang, & Faraone, 2004) of small effect size (odds ratio: 1.13), yet it turned out to be significant in a meta-analysis published in 2005 (Faraone et al., 2005). More recent data may question this result again. Gene-environment interactions may also play a role (Becker, El-Faddagh, Schmidt, Esser, & Laucht, 2008).

Dopamine Receptors

In the dopamine receptor family, the dopamine receptor 4 (*DRD4*) has received the most attention. Both noreadrenaline and dopamine can activate the *DRD4*. It is distributed in the frontal cortex and subcortical areas (basal ganglia), which play a role in the regulation of psychomotor behavior and attention. Here it is a 7-tandem repeat allele that produces a diminished response (less effective transmission) to dopamine (Swanson et al., 2000). Small but significant associations have been repeatedly found between this 7-repeat allele and ADHD (significant odds ratio in a meta-analysis of 1.16 or 1.45, depending on whether it is based on family or case-control studies; Faraone & Khan, 2006; Hejjas et al., 2007; Kereszturi, Kiraly, Csapo, Tarnok, Gadoros, Sasvari-Szekely, & Nemoda, 2007; Li, Sham, Owen, & He, 2006; Shaw et al., 2007; Swanson et al., 2007). The genetic risk may interact with environmental factors such as prenatal exposure to nicotine when the mother smokes (Becker et al., 2008; Neuman et al., 2007).

For *DRD5* (dopamine receptor 5), a significant odds ratio of 1.24 (family study-based) was obtained (Daly, Hawi, Fitzgerald, & Gill, 1999; Faraone & Khan, 2006; Payton et al., 2001). The association might exist only for the inattentive and the combined subtypes (Lowe et al., 2004).

DRD3 may be related to impulsivity and violence, but the support for this hypothesis is still scarce.

If *DRD2* has any effect on ADHD, it has to be very small (Faraone & Khan, 2006) and should be related

to impulsivity and drug dependence (Blum, Sheridan, Wood, Braverman, Chen, & Comings, 1995).

Enzymes Involved in Dopamine Metabolism

Dopamine beta hydroxylase (DBH) converts dopamine to norepinephrine (Comings, 2001). The evidence for the involvement of the DBH gene in ADHD is more mixed, but when evidence for the Taq1-polymorphism near the 5' end is pooled, the odds ratio (1.33) is significant (Faraone & Khan, 2006; Hawi et al., 2003; Roman, Schmitz, Polanczyk, Eizirik, Rohde, & Hutz, 2002; K. M. Smith, Daly, Fischer, Yiannoutsos, Bauer, Barkley, & Navia, 2003). The association could be stronger for the combined subtype (Roman et al., 2002). Patients showed lower DBH activity in serum and urine (Kopeckova, Paclt, & Goetz, 2006).

For monoamine oxidase (MAO), the evidence is currently mixed but there are some positive findings (Jiang, Xin, Lin, Qian, Tang, Wang, & Wu, 2001; Lawson et al., 2003; Manor, Tyano, Mel, Eisenberg, Bachner-Melman, Kotler, & Ebstein, 2002; Payton et al., 2001; Xu, Brookes, Chen, Huang, Wu, & Asherson, 2007). COMT (catecholamine-O-methyl-transferase; both MAO and COMT are involved in dopamine degradation) does not seem to be implicated to a large extent (Caspi et al., 2008; Comings, 2001; Gothelf et al., 2007; Hawi, Millar, Daly, Fitzgerald, & Gill, 2000; Payton et al., 2001), nor does tyrosine hydroxylase, which plays a role in dopamine synthesis. MAO and COMT influence serotonin levels and may be important in comorbid aggressive conduct problems (Caspi et al., 2008; Lawson et al., 2003).

Because blocking the norepinephrine transporter is efficient in the treatment of ADHD, the norepinephrine receptors and the norepinephrine transporter genes have been examined. However, so far no convincing evidence for an association with ADHD is available (Barr et al., 2002; McEvoy, Hawi, Fitzgerald, & Gill, 2002), despite some interesting findings (Kim et al., 2006).

Genetic findings also indicate the involvement of serotonergic neurotransmission in ADHD, and neuropsychological profiles indicate involvement of motivational aspects and other functions apart from mere inhibition and executive control deficits. The analysis of ADHD comorbidities could point into the same direction. However, serotonergic genes could exert their main influences during ontogenetic development rather than in the final state, as selective serotonin reuptake inhibitors (SSRIs) are not an effective medication for treatment of ADHD.

Serotonin Receptor *5HT1B*

Though SSRIs do not seem effective in ADHD treatment, for this serotonin receptor there have been significant findings (Hawi et al., 2002; L. Kent et al., 2002; Quist et al., 2003) pointing to an odds ratio of 1.44 (Faraone & Khan, 2006). For the serotonin transporter, the situation is similar (Bobb, Castellanos, Addington, & Rapoport, 2005; Curran, Purcell, Craig, Asherson, & Sham, 2005; Faraone & Khan, 2006). For tryptophan hydroxylase, the rate-limiting enzyme in serotonin synthesis, evidence is more limited (Walitza et al., 2005). Serotonin might modulate dopaminergic effects (Gainetdinov, Wetsel, et al., 1999) on attention through emotion and motivation regulation and may play a special role in aggressive impulsive behavior (Mitsis, Halperin, & Newcorn, 2000; Schulz et al., 2001). However, there have also been negative findings showing no association between serotonergic candidate genes and ADHD (Heiser et al., 2007).

SNAP-25

Involvement of synaptosomal-associated protein 25 gene was suggested by a mouse model that showed hyperactivity and learning problems due to a deletion on chromosome 2q. Indeed, despite some inconsistencies (Renner et al., 2008), alleles of the *SNAP-25* gene have been shown to be associated with ADHD (Barr et al., 2000; Feng, Crosbie, et al., 2005). The example of *SNAP-25* demonstrates that genes that are not directly involved in monoaminergic neurotransmission can play an indirect role in and be important to the integrity of the respective systems.

Endophenotypes

Endophenotypes are on an intermediate level between genes and clinical symptoms, in that they may be a useful approach to delimiting the pathophysiological heterogeneity in ADHD, as different pathophysiological mechanisms may lead to similar behavioral symptoms (Doyle, Willcutt, Seidman, Biederman, Chouinard, Silva, & Faraone, 2005). Such approaches have been found to be useful, for example, in schizophrenia research (Bender, Weisbrod, & Resch, 2007). Though studies about ADHD endophenotypes are still scarce, a few electrophysiological and neuropsychological endophenotypes have been suggested: action monitoring as reflected by error-related negativity in the anterior cingulate might be a suitable electrophysiological endophenotype for ADHD (Albrecht et al., 2008). Motor control (Rommelse, Altink, Oosterlaan, Buschgens, Buite-

laar, De Sonnevile, & Sergeant, 2007), time production (Rommelse, Oosterlaan, Buitelaar, Faraone, & Sergeant, 2007), and executive functions (Rommelse, Altink, Oosterlaan, Buschgens, Buitelaar, & Sergeant, 2008; Slaats-Willemsse, Swaab-Barneveld, de Sonnevile, & Buitelaar, 2007) also fulfill endophenotype criteria. The NoGo anteriorization, which is supposed to reflect response monitoring and inhibition in the anterior cingulate, could also be an ADHD endophenotype. As the effects of single genes appear to be small in ADHD, endophenotypes could have the advantage of summing up the combined effects of various genes acting, for example, on the dopaminergic system.

Recent investigation has shown that gene expression varies considerably during ontogeny. So-called epigenetic effects show that environmental events are able to interact with the genome: the presence or absence of adequate parenting can lead to a methylation of genes and change their expression (Bender, Weisbrod, & Resch, 2007). This leads us to gene-environment interactions:

Gene-Environment Interactions/ Development of Psychic Structure

Fronto-striatal circuits, which need to be trained in stable personal relationships, can be internalized to regulate affective behavior (prefrontal-limbic interactions) and executive control (prefrontal—thalamic/striatal/cortical; Koch et al., 1999; Resch, 1999, 2004). This way, environmental factors can interact with traits that are mainly genetically determined, such as inhibition or working memory capacity.

In psychoanalytic theory, psychic structure is the part of the self that is not primarily reflexive but determines how the self acts and shapes how the self interacts with the environment. It therefore is a kind of procedural self in contrast to the declarative self (Resch, 2004). One aspect of psychic structure is self-regulation. Self-regulation refers to the ability to manage oneself so that one can act efficiently. It also involves the regulation of emotions and motivational impulses in order to integrate them into a coherent self. Another aspect of psychic structure as the executive control of the self is conflict solving, for example, the ability to integrate a failure or critique into one's generally positive narrative self-concept. The regulation of self-worth ("narcissistic regulation") is an important related topic. The enlargement of the child's repertoire of possibilities to experience and to act is a manifestation of the development of the child's psychic structure, which may, in time, be

considered a treasure of all the experiences one has had with oneself, with the world, and with others (Freeman, 2003). The description of the psychic structure comprises three dimensions in the operationalized psychodynamic diagnostic manual (perception of the self and of objects, self-control, and interpersonal regulation/communication/attachment; Koch et al., 1999).

The most important contribution of this approach, apart from the use of a different vocabulary (remarkable overlaps between neuropsychological executive control and psychic structure are self-evident), may be the idea that structures develop along with one's interactional experiences with the world as a result of an internalization of one's personal history of relationships and experiences. This gives a hypothetical etiological explanation for why many studies and clinical experience show that executive control deficits are frequently found in children with social problems or autism (Brieber et al., 2007). Apart from genetic and temperamental factors, it is necessary to train one's executive functions in social relationships and non-social tasks in order to develop these abilities. The brain seems to need training to develop: if the child cannot experience self-efficacy in stable emotional relationships, it is highly plausible that his or her abilities to self-regulate behavior and impulses will not develop adequately. Apart from elucidating why one becomes nervous when emotionally burdened, the theory of inadequate development of the psychic structure gives an alternative explanation for why some children with attachment difficulties, chronic family conflicts, and social and emotional problems show ADHD symptoms.

Of course, the environmental factors interact with genetic vulnerabilities, leading to vicious circles through mutual interactions (low executive control leads to behavioral problems and conflicts, conflicts lead to less internalization of stable relationships and fewer experiences of effective control to strengthen effective neuronal networks, this leads to even more impaired executive control, etc.).

Role of Food and Nutrition/Intoxication

Non-conventional therapies (mostly elimination diets and fatty acid substitution) can play a great role in ADHD management (Concannon & Tang, 2005), though there is little empirical evidence supporting them (Cormier & Elder, 2007). A restricted elimination diet works due to unspecific factors (Pelsser, Frankena, Toorman, Savelkoul, Pereira, & Buitelaar, 2008).

Lead exposure can lead to ADHD symptoms (He, Yang, & Xu, 2000). Lead screening however seems

mainly necessary in developing countries and subjects living in old houses in which lead paint may be present (Kahn, Kelly, & Walker, 1995; Nevin, Jacobs, Berg, & Cohen, 2008). As a general risk factor, lead poisoning seems to play a small but significant role (odds ratio 4.1) (Banerjee, Middleton, & Faraone, 2007), as does prenatal nicotine exposure (odds ratio 2.5: Braun Kahn, Froehlich, Auinger, & Lanphear, 2006). There seems to be no threshold below which lead is innocuous; rather, a continuous dose dependency was observed (Thomson, Raab, Hepburn, Hunter, Fulton, & Laxen, 1989).

Zinc, an inhibitor of DAT (J. Krause, 2008), was found to be beneficial in a randomized controlled trial (Akhondzadeh, Mohammadi, & Khademi, 2004) and another double-blind placebo-controlled trial (Bilici et al., 2004). Serum zinc levels correlated with symptoms of inattention (Arnold et al., 2005). Plasma zinc levels were found to be lower in ADHD in some (Yorbik, Ozdag, Olgun, Senol, Bek, & Akman, 2008) but not in all studies (Antalis, Stevens, Campbell, Pazdro, Ericson, & Burgess, 2006). These interesting findings warrant further research before definite conclusions can be drawn.

Similarly, omega-3 fatty acids were found to be decreased in individual with ADHD (Antalis et al., 2006). Acetyl-L-carnitine had no effect in combined ADHD, and maybe some effects in the inattentive subtype (Arnold et al., 2007). In contrast, the omega-3 fatty acids docosahexaenoic acid and eicosapentaenoic acid have shown positive effects in randomized controlled trials (Kidd, 2007; Richardson, 2006; Richardson & Puri, 2002) but cannot yet be regarded as an established evidence-based ADHD therapy (Matsudaira, 2007; Voigt, Llorente, Jensen, Fraley, Berretta, & Heird, 2001). Effects of omega-3 fatty acids may not be specific to ADHD, as similar beneficial effects were found for mood disorders as well (Freeman et al., 2006). The current findings about omega-3 fatty acids, which are thought to foster a more reliable neurotransmission, are strong enough to recommend continued study (Ross, Seguin, & Sieswerda, 2007).

Since the finding of reduced glucose tolerance in ADHD (Langseth & Dowd, 1978), glucose metabolism (hyperglycemia) has been associated with hyperkinetic symptoms, especially in patients with a diabetes mellitus (Henley & Glatthaar, 2004). A reduced catecholamine response after glucose ingestion has been described (Girardi et al., 1995) and an energy deficiency syndrome has been suggested (Todd & Botteron, 2001). Abnormalities in astrocyte glucose and glycogen metabolism could lead to less reliable neurotransmission. However, overall, the influence of sugar in ADHD seems limited and conclusions are preliminary.

In contrast, there is no relationship between increased phosphate intake and ADHD symptoms.

THERAPEUTIC APPROACHES: DATA AND FINDINGS

After Bradley (1950) accidentally discovered that stimulants could be used to treat children with behavior problems, in 1957 methylphenidate (MPH) was developed to improve depressed mood in adult subjects (Angrist & Sudilovsky, 1978). In the second half of the 1960s the use of MPH for children with conduct and learning disorders started. Up to the mid-1970s, the stimulant boom triggered a lot of clinical investigations (Eggers et al., 2004). To date, stimulant treatment of ADHD is the treatment with the highest established effectiveness and safety (Barkley, 2004). Stimulant treatment is recommended as a necessary part of multimodal ADHD treatment strategies (Banaschewski et al., 2008a) by child and adolescent psychiatric professional associations such as the National Institutes of Clinical Excellence, the Scottish Intercollegiate Guidelines Network, and the European Network for Hyperkinetic Disorders (Taylor et al., 2004), as well as the American Academy of Pediatrics (2001).

The most commonly used stimulants are methylphenidate (e.g., Ritalin) along with d-amphetamine (e.g., Dexedrine), a d- and l-amphetamine combination (e.g., Adderall), and pemoline (e.g., Cylert; American Academy of Pediatrics, 2001; Taylor et al., 2004). MPH blocks the reuptake of dopamine in the central nervous system by the dopamine transporter (DAT; Federici, Geracitano, Bernardi, & Mercuri, 2005; Volkow, Fowler, Wang, Ding, & Gatley, 2002) and increases the release of dopamine from reserpine-sensitive granulae like amphetamine (Chiueh & Moore, 1975); there have been some reports of more intensive striatal than cortical MPH binding. Its increased lipophilic properties (good penetration of the blood-brain barrier) lead to its indirect dopaminergic and norepinephrinergic agonism, while peripheral sympathomimetic side effects are relatively reduced with respect to other amphetamines (Eggers et al., 2004).

Short-term effects, aside from overall improvement of ADHD core symptoms, include reduction of hyperactive behavior or excessive talking; improved motor coordination and control; improved sustained attention; especially to long, monotonous tasks; increased short-term memory capacity, and improved impulse control (DuPaul, Barkley, & Connor, 1998).

Secondary effects include a better integration into social groups, better ability to follow rules, less aggression and conflicts, and better utilization of already existing cognitive strategies (Barkley, 2004). These secondary effects seem crucial to patients' personality development and the prevention of dissocial behavior in adulthood.

Long-term treatment should only be undertaken when the short-term treatment has been very effective and therapy can be monitored sufficiently (Taylor et al., 2004). At regular intervals (e.g., once a year), attempts should be made to discontinue the medication, because training effects on fronto-striatal circuits as well as brain maturation and better possibilities for a compensation may allow the patient to continue therapy without medication (American Academy of Pediatrics, 2001; Taylor et al., 2004). In contrast, "drug holidays" taken to avoid tolerance effects or growth reduction seem only necessary when there are hints of an actual growth retardation. Therapies seem to be stopped prematurely more often than continued for too long. Therapies sometimes need to be continued into adulthood.

While hyperactive behavior often tends to normalize during adolescence, attentional problems but also difficulties with respect to emotion regulation tend to persist into adulthood.

Pharmacokinetics

The half-life of MPH is short (2.5 hours), and so the onset of its short-term effects is almost immediate after it is resorbed (about 1 hour after intake). The plasma peak levels are reached about 2 hours after intake. After about 3–5 hours the clinical effect quickly dissipates (Wolraich & Doffing, 2004). Thus short-term clinical effects can be assessed by rating scales.

Some authors recommend starting medication with 5–10 mg, adding another 5–10 mg after 3 days, and then increasing the dosage for another 5–10 mg per week until a good clinical effect is reached (Eggers et al., 2004). 1.0 mg/kg or 60 mg/day should not be exceeded, although this may be necessary in some cases (Taylor et al., 2004). Most often the target dosage is between 0.3/0.5 mg/kg and 1.0 mg/kg. In some children a better concentration can be observed at lower dosages, while an overdose leads to general sedation and worse concentration.

As the effects are often most relevant at school and in terms of sleep, two-thirds of the dosage is given in the morning, and one-third at noon. Alternatively, an extended-release drug (OROS-methylphenidate) can be

used (e.g., Concerta, Ritalin LA). It is important to know that extended-release drugs differ in their pharmacokinetic profiles. For example, Concerta shows plasma levels that remain into the evening (an osmotic pump is used for the extended-release formulation). Thus 36 mg of Concerta corresponds roughly to 3 times 10 mg of unretarded MPH. In contrast, Ritalin LA leads to a more rapid increase and plasma level decreases in the afternoon (microbead technology is used; Banaschewski et al., 2008a; Wolraich & Doffing, 2004). Thus 20 mg of Ritalin LA corresponds roughly to two doses of 10 mg unretarded MPH in the morning and at noon. Reduction of medication intake to once a day, and not necessary at noon, can considerably improve medication compliance in some subjects, as they do not feel stigmatized by their need to take medication at school and as they do not need to remember to take the medication more than once a day. However, it can also considerably increase medication costs (Banaschewski et al., 2006). The clinical efficacy is equivalent to that of immediate-release MPH (Banaschewski et al., 2008a; Dopfner, Gerber, et al., 2004).

Similar types of medication are amphetamines, which have stronger side effects than MPH (Efron, Jarman, & Barker, 1997; d-amphetamine, rather than l-amphetamine, is thought to be responsible for the clinical effects), and pemoline, which poses a risk of potentially fatal liver damage and is recommended only with frequent monitoring of liver function (American Academy of Pediatrics, 2001; Taylor et al., 2004). Individual children may respond to one stimulant but not another; thus in the case of non-response, the stimulant should be changed at least once (American Academy of Pediatrics, 2001).

Side Effects

The most important side effects of MPH are:

- Weight loss due to a reduced appetite (Arnold, Christopher, Huestis, & Smeltzer 1978; Efron et al., 1997; J. D. Kent, Blader, Koplewicz, Abikoff, & Foley, 1995). This can be reduced by an intake of the medication after the meals.
- Sleeping disorders, especially difficulties falling asleep (Efron et al., 1997). This is more common for extended-release formulae. Experimental approaches have used melatonin to try to alleviate these difficulties. It should be noted that sleeping difficulties are already frequently associated with ADHD (Andreou, Karapetsas, Agapitou, & Gourgoulis, 2003; Corkum, Moldofsky, Hogg-Johnson, Humphries, Tannock, 1999).

- Reduced growth, leading to shorter stature (Poulton & Cowell, 2003; Spencer, Faraone, Biederman, Lerner, Cooper, & Zimmerman, 2006; Vitiello, 2008). Most subjects are not affected or are affected only in term of a few centimeters; however, careful monitoring on the growth chart is necessary.
- Gastrointestinal problems (Greenhill, Findling, & Swanson, 2002)
- Increase in heart rate and blood pressure (often spurious; Arnold et al., 1978; Ernst, Zametkin, Matochik, Liebenauer, Fitzgerald, & Cohen, 1994)
- Headache. Catecholamines have been related to migraine type headaches, in particular, which can be triggered by a cerebral hyperexcitability via the neurovascular coupling (Greenhill et al., 2002; Pliszka, 2007).
- Dysphoric mood regulation, affective lability (Firestone, Musten, Pisterman, Mercer, & Bennett, 1998)
- Worsening of preexisting tic symptoms in some patients. In some patients, tics improve (Kurlan, 2003).

Most of these side effects represent sympathomimetic effects. Reduced appetite and sleeplessness can occur in up to 50% of treated children but are very often temporary and dose dependent.

Contraindications (American Academy of Pediatrics, 2001; Taylor et al., 2004) are heart diseases (risk of tachyarrhythmia, sudden death); hypertension (can be further increased); cardio- or cerebrovascular diseases (worsened blood flow), schizophrenia, mania (mania and psychosis can be triggered by stimulants as dopaminergic agents), or manifest suicidality (a suicide attempt could be triggered); hyperthyroidism (a hormonal cause of hyperactivity, which should be treated causally); glaucoma (high pressure in the eye ball, which can be increased by sympathomimetic drugs); drug addiction (risk of medication misuse); pregnancy (risk of malformations); pheochromocytoma (a tumor that produces catecholamines and thus hyperactivity); co-medication with MAO inhibitors (possible strong mutual increase of side effects); urinary retention (would be worsened by sympathomimetic agents); age under 6 years (no sufficient data, increased side effects). Dosages above 1mg/kg are contraindicated because they should not be routinely used.

Tics and Tourette syndrome are relative contraindications. In some cases tics may improve with MPH. Otherwise, a non-stimulant, such as noradrenergic reuptake inhibitors like atomoxetine, could be the treatment of choice (Banaschewski et al., 2008b). This is also the case when there are comorbid anxiety disorders (Banaschewski et al., 2008a). Please note that

many of the above mentioned contraindications have a low prevalence in childhood. In adult patients with ADHD, contraindications become more relevant.

Routine Monitoring

Before stimulant medication is prescribed, it is a good idea to record an electrocardiogram to exclude risk factors for tachyarrhythmia (exclusion of long QT-syndrome) when the child shows any cardiac symptoms. In the absence of preexisting clinical heart symptoms, an ECG is considered optional by the current guidelines.

An EEG may detect vulnerability to seizures. Epileptic patients should be treated with stimulants only under sufficient antiepileptic treatment (Taylor et al., 2004).

Especially with longer-lasting treatment, routine monitoring of laboratory parameters including a differential blood count, should be undertaken. Pregnancy should be excluded in adolescent girls. Blood pressure, heart rate, height and weight, tics, depression, and psychopathological symptoms such as withdrawal, perseveration, irritability, and lack of spontaneity should be checked for at every visit (Taylor et al., 2004).

Non-Stimulant Medication

Atomoxetine (Strattera) is a selective norepinephrine reuptake inhibitor that has been approved as a non-stimulant treatment for ADHD targeting norepinephrine instead of dopamine reuptake (Seneca et al., 2006). It has been shown to be effective, but its effect size may not be as strong as that of MPH (about 70%; Banaschewski et al., 2008b). Atomoxetine is a good second-line treatment when tics become worse under MPH, when there is a comorbid anxiety disorder, when there is a non-response to MPH, or when other side effects occur under MPH (Banaschewski et al., 2006). Atomoxetine has not been shown to be an effective antidepressant. For that reason, the choice to give atomoxetine to children with social or mood problems must be questioned and cannot be recommended at the moment.

Psychotherapeutic Approaches

In all guidelines, psychoeducation is always recommended, at least to complement medication treatment. In mild to moderate cases of ADHD, many patients look at pedagogical or psychotherapeutic interventions as first-line treatment before starting pharmacotherapy. Patient satisfaction with a treatment plan is better if when incorporates psychotherapeutic elements.

Causal treatment of underlying emotional or social problems to resolve conflict and eliminate reactive hyperactive or inattentive behavior must precede any further symptom-oriented approaches. However, evidence for the efficacy of psychotherapeutic approaches in well-diagnosed ADHD is more limited than for medication. Overall, parent and teacher training (classroom management) as well as behavioral contingency management (especially positive reinforcement, timeout, response cost, and token economy; American Academy of Pediatrics, 2001) are well-established ADHD treatments, while the support for the effectiveness of cognitive interventions so far is very limited (Pelham & Fabiano, 2008; Pelham et al., 1998).

It should be kept in mind that due to the high heritability of ADHD, parents often show adult ADHD symptoms themselves (Harvey et al., 2003), which can limit the possibilities of parent training or make very short and clear parent instructions necessary.

ADHD children do not need to reach cognitive insight regarding why they developed inattentive symptoms or hyperactive behavior but they do need to accomplish certain tasks (right behavior at the right time; Barkley, 2004). Thus it is important to create an environment that enables the child to succeed in attention and motivation maintenance—though this is a difficult, time-consuming task for families and teachers. It has repeatedly been shown that in addition to psychoeducation (information about the nature of the disease), specific training for parents and teachers in how to deal with ADHD children can be extremely effective in improving the difficulties of the child at home or at school (Sonuga-Barke et al., 2001; van den Hoofdakker et al., 2007). Parents and teachers can be trained in contingency management. The reduction of negative/ineffective parenting seems especially important in combination therapy (Hinshaw et al., 2000).

One rationale for the caretaker-centered approach is that the cognitive abilities for self-regulation are much better in adult caretakers. They can more easily learn to modify their behavior and, for example, learn to give a limited number of short, simple, and clear orders and reinforce them with natural consequences immediately after the behavior in a very reliable manner. It is much more difficult for a child to learn to deal with inconsistent parenting and conflicts because of limited self-regulation. Moreover, parents and teachers spend a lot more time with the child than the doctor or psychologist, so they can multiply (i.e., apply more often) any intervention.

The first target of any ADHD treatment must therefore be counseling of parents and teachers about the

child's special needs and how they can adjust to these special needs in order to optimize parenting as much as possible. One aim is that the parents accept their child with his or her attentional problems and face the problem by supporting the child with clear guidance instead of getting lost in quarrels that occur when the child cannot follow the parents' complex sentences or simply too much self-control is requested. A generally positive attitude and relationship between parents and patient is crucial to for a positive treatment outcome. It therefore seems important not only to teach parents how to give effective directions but also to provide help to an exhausted overwhelmed mother, for example, integrating the father or the grandparents into the care of the child so that the mother has some time for herself and also some time to play with the child and have positive interactions with him or her without having to take care of any brothers or sisters. Agreement between father and mother is necessary with respect to where and when to set the boundaries for their children in order to avoid any inconsistencies.

Undesired behavior should be ignored whenever possible rather than punished, and attention should not be drawn to it. Positive behavior should be reinforced, even if it is considered "normal" in non-ADHD children. Contingency management is a therapeutic intervention that has clearly proved its efficacy (Barkley, 2004; Luman, Oosterlaan, & Sergeant, 2005; Whalen & Henker, 1991).

Problem situations should be identified; consequences need to be applied repeatedly in a consistent way without longer delays (clear contingency) in order to shape the child's behavior (Taylor et al., 2004). Training and development of executive control/psychic structure in stable relationships with clear contingencies and consequences is an essential part of ADHD therapy. ADHD children tend to respond well to positive rewards, while their inhibitory deficits and novelty seeking make punishments, especially drastic punishments, rather ineffective.

More cognitive patient-centered techniques such as self-instruction training or "think before you act" strategies are often difficult to generalize to real-world problems and have not been proved effective in controlled trials (Taylor et al., 2004). A reason may be that due to the biological origins of ADHD deficits, compensatory approaches might work better than training to correct the deficits. Self-management training instructs children in how to manage their behavior in a more efficient and structured way (Dopfner, Breuer, Schurmann, Metternich, Rademacher, & Lehmkuhl, 2004; Dopfner, Lehmkuhl, & Schurmann, 1996). Of course there have

also been attempts to train executive control in ADHD patients.

Many parents find it helpful to understand the biological background of the disease, so that they do not feel that they have failed as parents but know that they face a particular difficulty with their child (who is also not lazy or deliberately disobedient). In some patients who are in need of stable emotional relationships, a rapid symptom remission can occur when such relationships can be established.

Sometimes the treatment of ADHD involves evaluation of the pros and cons of medication versus intensive pedagogical/therapeutic interventions. When additional individualized parenting and guidance and an education in a specialized environment could be sufficient to resolve hyperactive and/or inattentive behavior, but the parents are not able to provide this special care, should an expensive home treatment program be established, should the child be separated from his parents, or should medication be given? The second option seems justified when the individual case has been analyzed and all of the family's available personal educational resources are adequately used. An adaptation to our environment is necessary and wise. ADHD treatment can help the child with these adjustments. In contrast medication, is not and should not be an easy way to silence a troublesome child. Psychosocial interventions can have side effects, too, for example, with respect to economic resources or a possible separation of the child from the family.

Of course, a psychosocial intervention based on a stable relationship is especially important to children with ADHD symptoms due to emotional problems caused by deprivation, family conflicts, being ganged up on at school, and other issues. Nevertheless, sometimes in the beginning a symptom-oriented use of stimulant medication can be very helpful, so that patients can join a social group and use the therapeutic interventions. Afterwards, medication could be withdrawn.

Comparison of the Effect Sizes of Medication and Psychotherapy

The Multimodal Treatment Study of Children with ADHD (MTA Cooperative Group, 1999a), as study of 579 children with ADHD, showed that the combination of parent and teacher training and child-centered behavior therapy resulted in a clear reduction in ADHD symptoms; however, the approach with carefully monitored medication only was more effective! It is important to note that medication prescribed by a specialist was also

clearly more effective than routine care (including medication in two-thirds of the cases) by community services. The two approaches combined (psychotherapy plus medication) were not superior to medication alone with respect to overall ADHD core symptoms; however, patients and parents were more satisfied with the combined approach, and common comorbid conditions (aggression or emotional problems) could be treated more adequately. Moreover, parent-child relations and school achievements were also better in the combined approach.

Thus psychotherapy seems especially important for children with comorbid emotional problems (Jensen et al., 2001) and psychotherapy may focus on these frequent concomitant problems (Lehmkuhl, Sevecke, Frohlich, & Dopfner, 2002) rather than target ADHD core symptoms. In children with comorbid anxiety disorder, behavior therapy alone was as effective as medication and combined therapy (MTA Cooperative Group, 1999b). It has been concluded that individual therapies need to be tailored to the peculiarities of each case in order to develop a combined approach superior to careful medication management (Greene & Ablon, 2001).

Finally, the aforementioned effects in the MTA study were stable at 24 months. However, in a follow-up after 36 months, the differences between behavior therapy and medication management had vanished, though a premature cessation of medication may have contributed to this finding (Jensen et al., 2007).

At the moment, taking into account the results of the MTA study, we would recommend that medication be prescribed immediately after the establishment of the diagnosis when ADHD is severe and secondary negative consequences (e.g., school failure) are expected, and quick symptom relief is urgently needed. In all other cases of mild or moderate ADHD, a psychotherapeutic and counseling approach, in consideration of the patient's and parents' resources and preferences, may be applied in a first step, with medication reserved for cases in which there is an insufficient response.

CONCLUSION

While stimulant medication is often most effective in reducing ADHD core symptoms, psychotherapeutic interventions and parent/teacher counseling are important in less severe cases for long-term outcomes, to achieve medication adherence, and to deal with frequent comorbidities such as family and emotional problems. The future will determine the role of new approaches such as neurofeedback (see chapter 29).

Evidence-Based Clinical Management of Obsessive- Compulsive Disorder

Hunna J. Watson
Rebecca A. Anderson
Clare S. Rees

Obsessive-compulsive disorder (OCD) is a chronic and disabling mental illness characterized by anxiety-provoking and intrusive thoughts, and repetitive behaviors aimed at reducing the discomfort associated with these thoughts. Once considered a difficult disorder to treat, advances in the conceptualization and treatment of OCD have improved the prognosis for individuals with this disorder.

Current research suggests that OCD may have biological, genetic, and psychological foundations. There is little evidence to support any one theory of OCD exclusively, and some theoretical models provide clearer treatment indications than others. For example, neuroimaging and heritability studies certainly provide insight into the possible etiology of OCD. However, Andrews, Crino, Hunt, Lampe, and Page (2003) demonstrate that neuro-anatomical explanations do little in the way of providing OCD sufferers with a useful means of coping with or overcoming their symptoms. By the same token, pursuit of this line of inquiry is important and the ultimate hope is that one day gains from these studies may be translated into primary prevention efforts. It is important that we continue to understand the causal and maintaining

factors of this disorder, yet we must continue to provide a sense of hope for treatment seekers as we translate research into clinical explanations and practice.

Fortunately, there are two major evidence-supported interventions for OCD. Cognitive-behavioral therapy (CBT) with exposure and response prevention (ERP) and pharmacological interventions have produced high rates of symptom improvement compared with alternative forms of therapy in controlled trials. Although these treatments have both significantly improved the quality of life of OCD patients, there is still room for improvement. For example, it is known that when non-specialists deliver ERP-based treatments, the length of treatment increases (Fisher & Wells, 2005); yet not all clinicians have access to specialist training (Marks, 1997; Nakagawa, Marks, Park, Bachofen, Baer, Dottl, & Geist, 2000). Treatment refusal and dropout have been associated with both ERP and medication trials, indicating the need to consider new methods for improving treatment compliance and acceptability. Patients often present with significant case complexity and comorbidity, thus requiring a range of flexible treatment options in terms of dose, intensity, content, and format.

For CBT, a range of alternative formats have been trialed to maximize clinical impact and improve accessibility, compliance, and acceptability of existing evidence-based treatments. Significant symptom reductions have been noted for patients treated in initial trials of family-based, telephone, video-conferencing, and self-guided computer-based methods of delivery (Baer & Greist, 1997; Clark, Kirkby, Daniels, & Marks, 1998; Himle, Fischer, Muroff, van Etten, Lokers, Abelson, & Hanna, 2006; Taylor et al., 2003; van Noppen, Steketee, McCorkle, & Pato, 1997). A recent meta-analysis of randomized controlled trials of group CBT for OCD indicated a large treatment effect size compared to wait-list or placebo-control conditions (Rees & Anderson, 2008). There is preliminary support for the use of intensive CBT for patients with more severe symptoms, distress or disability, significant comorbidity, and/or poor response to less intense forms of treatment (Abramowitz, Foa, & Franklin, 2003; National Institute for Health and Clinical Excellence, 2006; Storch, Gelfand, Geffken, & Goodman, 2003).

Recent clinical guidelines have suggested the need to incorporate such evidence-based strategies in a stepped-care model of treatment (National Institute for Health and Clinical Excellence, 2006). Such a model proposes intensive treatment options as a step to be provided only when required, or based on indicators of case severity or complexity, which would contraindicate a less intensive therapeutic approach. This means that the individual receives gold-standard therapy, but in the least intrusive and aversive format, given his or her idiosyncratic presentation and response to trialed treatment steps. It is also intended to afford the general health care environment a more functional means to manage service resources in order to confer benefit to as many individuals as possible.

This chapter reviews the assessment, diagnosis, and treatment monitoring procedures for use with adults, children, and adolescents with OCD. An overview of contemporary models of OCD etiology and maintenance is given. Clinical cases illustrating gold-standard treatments for OCD are provided to improve case managers' understanding of the skills and techniques essential for treating this disorder.

EPIDEMIOLOGY, AGE OF ONSET, COURSE, PROGNOSIS

Approximately 1%–2% of adults (Weissman et al., 1994) and .25%–4% of children (Douglass, Moffitt, Dar, McGee, & Silva, 1995; Heyman, Fombonne, Simmons,

Ford, Meltzer, & Goodman, 2003) are affected by OCD. It is the fourth most common psychiatric disorder (Karno, Golding, Sorenson, & Burnam, 1988), is 2–3 times more prevalent than severe mental illnesses like schizophrenia and bipolar disorder, and was ranked by the World Health Organization as the tenth-leading cause of disability in the world (Murray & Lopez, 1996).

Sixty percent of adult sufferers report an onset of the disorder before age 25 (Rasmussen & Eisen, 1990), with most presentations characterized by a gradual onset and a chronic waxing and waning course. Without treatment, 20%–40% of individuals meet full diagnostic criteria up to a reported 15 years after onset (Skoog & Skoog, 1999; Stewart et al., 2004; Wewetzer et al., 2001).

Due to the fear of embarrassment, many individuals with OCD attempt to hide their symptoms and thus often suffer for years with the symptoms and distress before seeking treatment (Steketee, 1993). On average, individuals first present for psychiatric treatment over 7 years after the onset of significant symptoms (Rasmussen & Tsuang, 1986). The lengthy delay between onset and treatment seeking may lead to increased comorbidity and case complexity, as over time the individual implements counterproductive strategies to control symptoms (Salkovskis, Forrester, Richards, & Morrison, 1998).

When left untreated, OCD is associated with lower employment rates and higher receipt of disability payments (Leon, Portera, & Weissman, 1995), poorer academic performance (Sorenson, Kirkeby, & Thomsen, 2004), impaired social and family functioning (Bystritsky et al., 2001; Calvocoressi et al., 1995; Khanna, Kaliaperumal, & Channabasavanna, 1990; Koran, Thienemann, & Davenport, 1996), lower romantic intimacy and satisfaction (Abbey, Clopton, & Humphreys, 2007), and lower marital rates (Hollander, Stein, Kwon, Rowland, Wong, Broatch, & Himelein, 1997). Of concern is the fact that almost one in three individuals with OCD has attempted suicide (Kamath, Reddy, & Kandavel, 2007). Given the debilitating nature of the illness, and the current recognition of the extensive impact the disorder has on the community, it is time that practitioners, educators, and researchers begin to focus on the early detection of OCD and to better understand the disorder and its treatment.

DIAGNOSTIC CRITERIA AND CLINICAL PRESENTATION

The diagnostic nomenclature for OCD is similar across the two major diagnostic systems employed by mental

health practitioners: the *International Classification of Mental and Behavioral Disorders (ICD-10)*; World Health Organization, 1992) and the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*; American Psychiatric Association, 2000). In both, obsessions and/or compulsions are the core features of OCD, and a diagnosis is only ascribed if the symptoms are time consuming, distressing, and/or associated with marked functional impairment. Interestingly, phenomenological manifestations of the disorder are remarkably similar across cultures (Pallanti, 2008).

A summary of the key diagnostic criteria indicated by the *DSM-IV-TR* and *ICD-10* is provided in Exhibit 16.1. Both classification systems provide a differential diagnosis and additional specifiers that may be applied to assign a diagnosis. For example, according to the *DSM-IV-TR*, OCD should not be diagnosed if the obsessions are related to contracting a particular illness and no rituals are involved. In such a case, a specific phobia would be the more appropriate diagnosis.

The term “obsessions” refers to intrusive and persistent ideas, thoughts, impulses, and images. Evidence suggests that most of the general population experiences intrusive or unwanted thoughts at some time (Rachman & de Silva, 1978). The distinguishing features of obsessions are their higher frequency and intensity and/or greater duration, and the ways in which the thoughts are interpreted. For example, a client with OCD may appraise the occurrence of an intrusive thought about wanting to harm his or her child as equivalent to wishing for harm to come to the child. This type of thought is ego-dystonic (i.e., incompatible with and unacceptable to one’s overall self-concept), and therefore the thought causes distress. The term “compulsions” is used to refer to repetitive behaviors or mental acts completed to prevent or reduce anxiety or distress, avoid feared consequences, and/or restore a sense of safety. Common examples of obsessions and compulsions are presented in Table 16.1.

The often early age of onset and lengthy delays in treatment seeking may increase levels of case complexity, as over time the symptoms become part of the individual’s experience, behavioral repertoire, and established response pattern (Black, Noyes, Pfohl, Goldstein, & Blum, 1993; Summerfeldt, Huta, & Swinson, 1998). The typical OCD presentation is marked by more than one obsession and compulsion, and a range of comorbid mood, anxiety, and/or personality disorders (Denys, Tenney, van Megen, de Geus, & Westenberg, 2004; Rasmussen & Eisen, 1988; Rasmussen & Tsuang, 1986; Tükel, Polat, Özdemir, Aksüt, & Türksoy, 2002).

16.1

Diagnostic Criteria for Obsessive-Compulsive Disorder

OBSSESSIONS

- Recurrent and persistent thoughts, impulses, or images that are experienced as intrusive and inappropriate and that cause marked anxiety or distress.
- They are not simply excessive worries about real-life problems.
- The person attempts to ignore, suppress, or neutralize them with some other thought or action.
- The person recognizes that the obsessions are a product of his or her own mind.

COMPULSIONS

- Compulsions are repetitive behaviors or mental acts that the person feels driven to perform in response to an obsession, or according to rules that must be applied rigidly.
- They are aimed at preventing or reducing distress or preventing some dreaded event or situation.
- They are not inherently enjoyable, nor do they result in the completion of inherently useful tasks.

OBSSESSIONS AND COMPULSIONS

- Cause marked distress, are time consuming, or significantly interfere with the person’s functioning.
- Are recognized as excessive by adult sufferers.

Clinicians must therefore be cognizant of the potential impacts of particular comorbidities on treatment selection. For example, studies examining the effects of personality disorders on treatment outcomes for OCD have shown mixed results (see Dreessen, Hoekstra, & Arntz, 1997; Moritz et al., 2004; Steketee, 1990). Some studies suggest that severe depression may impede the

16.1

Common Examples of Obsessions and Compulsions

OBSSESSION TYPE	THOUGHTS, IMPULSES, OR IMAGES OF . . .
Religious, aggressive, sexual intrusions	. . . hurting a vulnerable person, committing blasphemy, committing a sexual offence, being at fault for harm coming to others
Contamination fears	. . . being contaminated with germs/dirt/faeces/radioactive materials, contaminating others
Need for symmetry/exactness	. . . wanting things to feel just right, not making a mistake
Somatic concerns	. . . having contracted a disease, such as HIV, in the absence of risky behaviors
Need to hoard/save	. . . harm coming to oneself or others because one did not keep a particular item
COMPULSION TYPE	REPEATEDLY . . .
Checking/reassurance seeking	. . . touching a door handle to ensure it is locked, asking others whether door was locked correctly
Cleaning	. . . washing hands/clothing/household goods, sometimes with bleach
Counting/repeating	. . . touching or looking at things, doing things seven or multiples of seven times, repeating words silently
Ordering/arranging	. . . arranging furniture, straightening household objects
Hoarding	. . . collating newspapers, magazines, menus
Neutralizing thoughts	. . . replacing distressing thoughts with “good” thoughts, praying

Adapted from *Obsessive-Compulsive Disorder: Core Interventions in the Treatment of Obsessive-Compulsive Disorder and Body Dysmorphic Disorder*, by the National Institute for Health and Clinical Excellence, 2005, Washington, DC: Author.

efficacy of ERP by affecting reactivity and habituation to aversive stimuli (e.g., Abramowitz, Franklin, Street, Kozak, & Foa, 2000; Foa, 1979, cited in Foa, Franklin, & Kozak, 1998; Steketee, Chambless, & Tran, 2001). Yet Foa and colleagues (1992, cited in Foa et al., 1998) found that both depressed and non-depressed clients with OCD responded favorably to ERP and that the reduction of depression via medication prior to ERP did not enhance the treatment outcomes. Steketee and associates (2001) found that comorbid generalized anxiety disorder (GAD) was predictive of CBT dropout. They proposed that the pervasive anxiety characteristic of GAD may have interfered with clients' willingness or ability to engage in therapy assignments, yet they recognize that empirically supported techniques for treating GAD could easily be incorporated into standard CBT for OCD. It is therefore important for clinicians to implement innovative techniques or treatment modes to ensure that clients with comorbid diagnoses are well catered to in treatment programs.

ASSESSMENT AND DIAGNOSIS

A thorough assessment of OCD is essential for establishing an accurate diagnosis. Perhaps even more importantly, a thorough assessment enables development of an accurate individualized formulation and treatment plan for the patient. Although the main symptoms of OCD are common among patients diagnosed with the disorder, the factors leading to its development and maintenance are unique to each patient. As such, treatment plans need to be tailored to the individualized formulation, which results from the accurate assessment of symptom development and maintenance.

Accurate Diagnosis is Critical

A number of conditions share similar features to OCD yet have very different etiological pathways and asso-

ciated treatments. Conditions such as GAD, psychosis, impulse control disorders and obsessive-compulsive personality disorder can be challenging to distinguish from certain OCD presentations. For example, in many OCD cases obsessions are associated with poor insight and can be of delusional intensity. As a result, thorough attention to accurate diagnosis of OCD is warranted.

There are significant consequences to misdiagnosis. For example, if a clinician inaccurately concludes that the patient's primary problem is GAD, then the subsequent treatment plan will most likely target the control of worry and reduction of physiological tension. For GAD, relaxation exercises are usually prescribed and cognitive therapy aimed at challenging excessive and uncontrollable worry is provided. However, relaxation treatment is used as a placebo condition in randomized controlled trials of OCD because it is an ineffective treatment for the disorder. Thus if the patient were to be misdiagnosed, it is likely that he or she would not receive the most appropriate and effective treatment.

Unfortunately, for many clinicians working in demanding clinical settings, diagnosis is often limited to the use of unstructured clinical interviews that provide rich and useful information but pose many difficulties in terms of reliability. Structured clinical interviews make the task of assessing diagnostic cases more reliable and less formidable. Many structured diagnostic interviews exist, but for OCD the fourth edition of the Anxiety Disorders Interview Schedule (ADIS-IV; Di Nardo, Brown, & Barlow, 1994) is the most widely used and reliable measure. Administration of structured clinical interviews should only be undertaken by mental health professionals with training in psychiatric assessment and diagnosis.

Anxiety Disorders Interview Schedule

The current version of the ADIS enables the clinician to arrive at clinical diagnoses as per the *DSM-IV-TR* diagnostic criteria. The ADIS-IV is a very comprehensive instrument for distinguishing between anxiety disorder diagnoses. It uses 9-point severity scales that help to distinguish which of the current problems are most disabling and interfering the most in the client's life. It also inquires about mood disorders and alcohol and drug use, as these are often comorbid with anxiety disorders. There are two versions of the ADIS-IV: one that assesses current symptoms and one that assesses both current and past symptoms (lifetime version). Interrater reliability of OCD diagnosis is good ($k = .75$; Brown, Di Nardo, Lehman, & Campbell, 2001). The ADIS-IV can be purchased online for approximately \$50 for a pack of 10 booklets. There are analogous child (ADIS-C) and

parent (ADIS-P) versions (Silverman & Albano, 1996). The child and parent versions have good interrater reliability, test-retest reliability, and concurrent validity (Silverman, Saavedra, & Pina, 2001; Wood, Piacentini, Bergman, McCracken, & Barrios, 2002). The OCD diagnostic category has excellent reliability (Brown et al., 2001). A drawback of the ADIS interviews is that they are time intensive to administer (approximately 1.50–2 hours each). For many clinicians, this is an unrealistic time commitment for determining diagnosis. An alternative measure for arriving at diagnoses is the Mini International Neuropsychiatric Interview (MINI).

Mini International Neuropsychiatric Interview

The MINI (Sheehan et al., 1998) is a structured clinical interview that enables diagnoses to be made for both *DSM-IV* and *ICD-10* criteria. The major benefit of the MINI over its counterparts is that it is very quick to administer (can be completed in as little as 15 minutes), making it a viable option in clinical practice. The other benefit of the MINI is that a screening form is available that can be completed initially and indicates which areas to focus on in the longer interview. The MINI primarily assesses Axis I conditions but also covers antisocial personality disorder on Axis II. The MINI has good concordance with lengthier structured clinical interviews and can be downloaded for free from the Internet (individuals can register to download the diagnostic interview at <https://medical-outcomes.com/HTMLFiles/MINI/MINI.htm>).

Multiple Assessment Methods Are Most Effective

Assessment of OCD is best conducted through multiple methods. Gathering information from the patient during the interview is obviously extremely important, but other methods can also be very informative. Speaking to significant others such as partners, children, parents, and school teachers may provide information about how OCD symptoms manifest in different contexts. Often the patient will provide only limited information due to difficulty he or she has expressing thoughts and feelings or anxiety related to verbalizing what is happening. Often-times the patient may have lost touch with the source of his or her anxiety and the nature of the obsessional concerns due to the effective use of rituals over a long period of time. In these instances, methods such as behavioral avoidance tests can be very useful to assess the severity of symptoms, the extent of avoidance, and the

content of obsessional thoughts. In a similar fashion, the use of self-monitoring forms can be an important assessment device. For example, a patient may believe that he or she is currently washing his or her hands approximately 20 times per day, but when asked to complete a day of self-monitoring it becomes clear that this is occurring 50–60 times per day.

Formal measures can be used to assess the types of symptoms a patient is experiencing as well as the severity of those symptoms. Symptom severity measures such as the Yale-Brown Obsessive-Compulsive Scales (Y-BOCS; Goodman et al., 1989) are useful measures that can be used to assess the impact of treatment. Other measures can provide specific information regarding the types of beliefs that characterize OCD.

Observational Measures

Behavioral Avoidance Tests and Subjective Units of Distress Scale

BATs are observational measures aimed at assessing avoidance and levels of distress associated with specific behaviors. For example, if a patient indicates that he or she feels anxious about being near building sites because “something bad will happen,” a behavioral avoidance test (BAT) can be used to gain clarity as to the nature of the patient’s concerns and to pinpoint which aspects of building sites are most problematic. The clinician can set up a task involving gradual steps toward a building site while recording the patient’s thoughts and anxiety levels. To record anxiety levels, the clinician can use the Subjective Units of Distress Scale (Wolpe, 1969), which is a severity scale of 0–10 or 0–100 and is a very useful way for patients to quantify their level of distress. The scale can be used with children in the form of a “fear thermometer.” BATs can provide useful information that can later be used to develop exposure hierarchies.

Symptom Severity Measures

Yale-Brown Obsessive-Compulsive Scales

The Y-BOCS measure is preceded by standardized descriptions of obsessions and compulsions, which are read out loud to the patient. The first part of the Y-BOCS is a symptom checklist that the clinician utilizes to determine the types of obsessions and/or compulsions being experienced by the patient. This checklist contains over 50 common obsessions and compulsions. The clinician asks the patient whether the symptoms are currently occurring or if they have in the past. Next,

the clinician rates the severity of the patient’s current obsessions and compulsions, using a 5-point Likert scale ranging from 0 to 4. The clinician asks the patient about the frequency, distress, interference, resistance, and control of both obsessions and compulsions. A total of 10 questions are asked, the first 5 of which pertain to obsessions, and the second 5 to compulsions. For example, question 1 asks the patient how much of his or her time is occupied by obsessive thoughts. A total score out of 40, as well as separate obsession and compulsion subscale scores, can be derived for patients. Scores are simply summed for each of the items. The following severity ranges have been denoted for the total score: normal (0–7), mild (8–15), moderate (16–23), severe (24–31), and extreme (32–40). As well as being a useful psychometric instrument, the Y-BOCS possesses clinical utility. Information from the symptom checklist can be used to generate the OCD hierarchy, which is an essential part of the cognitive-behavioral treatment protocol. The Y-BOCS interview takes approximately 30 minutes to administer initially. With repeated administrations, the measure can be completed in as little as 10 minutes, due to disuse of the checklist and the patient’s increased familiarity with test items. The psychometric properties of the Y-BOCS have been extensively investigated and studies consistently report excellent reliability and validity (Taylor, 1995).

The Children’s Yale-Brown Obsessive-Compulsive Scale (CY-BOCS; Goodman et al., 1989) is the child and adolescent version of the adult Y-BOCS interview. Like the adult version, it is considered the gold standard for clinical trials and practice. It is administered by the clinician in a clinical interview and enables a total severity score as well as subscores for obsessions and compulsions to be obtained. The CY-BOCS has good psychometric properties.

Obsessive-Compulsive Inventory–Revised

The Obsessive-Compulsive Inventory was developed by Edna Foa and colleagues and has recently been revised. The revised measure consists of 18 items and has good internal consistency and test-retest reliability. The Obsessive-Compulsive Inventory–Revised (Foa, Huppert, Leiberg, Langner, Kichic, Hajcak, & Salkovskis, 2002) consists of six dimensions; washing, checking, ordering, obsessing, hoarding, and mental neutralizing. Each item is rated on a 5-point scale assessing degree of distress (0 = not at all; 4 = extremely). To score the inventory, each item is summed. Foa et al. (2002) calculated an optimal clinical cutoff score of 21 to distinguish OCD patients from the nonclinical population.

Vancouver Obsessional Compulsive Inventory

The Vancouver Obsessional Compulsive Inventory (VOCI; Thordarson, Radomsky, Rachman, Shafran, Sawchuk, & Hakistian, 2004) is a revision of the Maudsley Obsessional Compulsive Inventory (Hodgson & Rachman, 1977). The VOCI addresses the severity of six dimensions of OCD symptoms (contamination, checking, obsessions, hoarding, just right feelings, and indecisiveness). It utilizes a 5-point Likert response scale and demonstrates excellent internal consistency and test-retest reliability among OCD samples. An advantage of the VOCI is that it measures both behavioral and cognitive aspects of OCD. At this stage no information on its sensitivity to treatment effects is available.

Children's Obsessional Compulsive Inventory

Shafran, Frampton, Heyman, Reynolds, Teachman, and Rachman (2003) at Oxford University have developed a parent and self-report measure of OCD symptom severity, the Children's Obsessional Compulsive Inventory. It assesses the content domain of OCD symptoms and contains a global, obsessions, and compulsions severity score. Preliminary evaluation has shown that it has good reliability and concurrent validity with the CY-BOCS.

Measures of Cognition

Obsessive Beliefs Questionnaire-44

The Obsessive Beliefs Questionnaire-44 (OBQ; Obsessive Compulsive Cognitions Working Group, 2005) consists of 44 belief statements developed to characterize obsessive thinking and consists of three subscales: (1) inflated personal responsibility and the tendency to overestimate threat (responsibility/threat), for example, "Harmful events will happen unless I am careful"; (2) perfectionism and intolerance of uncertainty (perfectionism/certainty), for example, "I must be certain of my decisions"; and (3) over-importance and overcontrol of thoughts (importance/control), for example, "Having nasty thoughts means I am a terrible person." Respondents indicate their level of agreement with items on a 7-point rating scale. Higher scores indicate a greater strength of belief. The OBQ can be a useful measure for determining which beliefs to specifically target in cognitive therapy. The OBQ is internally consistent and has good test-retest reliability, convergent validity, and discriminant validity in adult samples (Obsessive Compulsive Cognitions Working Group, 2005).

Thought-Action Fusion Scale

The Thought-Action Fusion Scale (Shafran, Thoradson, & Rachman, 1996) measures the extent to which an individual believes that thoughts are equivalent to actions. It consists of 19 items, each measured on a 4-point scale. The scale is made up of two main factors: moral TAF (12 items) and likelihood TAF (7 items). "Likelihood TAF" refers to the belief that thinking about an event makes it more likely to occur in reality. "Moral TAF" refers to the interpretation of unwanted intrusive thoughts as morally equivalent to forbidden actions. The likelihood factor can be further broken down into likelihood others (4 items) and likelihood self (3 items). Shafran and her colleagues' initial study found the scale to be highly reliable in student, adult, and obsessional samples ($\alpha = .85-.96$). The scale's total scores for clinical OCD samples range from 29 to 34, whereas nonclinical samples are generally between 20 and 24.

Measuring Family Involvement

The Family Accommodation Scale for Obsessive-Compulsive Disorder (Calvocoressi et al., 1999) is a clinician-administered measure designed to assess the degree of family involvement in the patient's OCD. The first section asks relatives to identify the patient's current symptoms, using a list adapted from the Y-BOCS. The second section is the rating scale and consists of 12 items that assess accommodating behaviors, such as "During the past week did you buy extra soap or other items he needed for this ritual?" Each item is scored on a scale of 0 (none) to 4 (extreme). The scale has demonstrated good internal consistency, interrater reliability, and evidence of construct validity (Grabill, Merlo, Duke, Harford, Keeley, Geffken, & Storch, 2008). It has been used clinically and in research with adults and children.

PATHWAYS OF CAUSE AND MAINTENANCE

While the research of psychologists, psychiatrists, neurochemists, and geneticists has had different levels of focus, it is agreed that biological and psychological factors interact to cause OCD. Evidence for contemporary theories is primarily indirect, arising from cross-sectional research, postulations based on successful treatments, and research into acutely ill and not pre-morbid samples. A major limitation of most explanations (or perhaps the diagnostic nomenclature) is the

failure to explain the specificity of the emergent disorder (where similar etiologies are invoked for related anxiety and mood disorders) or the specific OCD symptoms that develop (e.g., checking rituals vs. excessive fear of germs and hand washing).

The diathesis-stress model purports that particular individuals are predisposed to develop particular illnesses, and that these predisposing factors may lie relatively dormant until activated by stressors and negative life events. A variety of vulnerabilities or diatheses have been advanced in theoretical models of OCD, which are summarized below. No single explanation affords an integrative perspective, yet in some way each contributes valuable insight into the putative mechanisms underlying OCD.

Genetics

Twin studies have found that the rate of concordance of OCD symptoms is high among monozygotic (50%–90%) and dizygotic twins (20%–50%) (Alsobrook & Pauls, 1998; Carey & Gottesman, 1998; Rasmussen & Tsuang, 1986). A single gene, rather than a complex array of multiple genes, is likely to be implicated in the development of OCD (Risch, 1990). Family studies have found that one-fifth of parents of children with OCD also have OCD (Lenane, Swedo, Leonard, Pauls, Sceery, & Rapoport, 1990; Riddle et al., 1990). Fathers appear more likely to have OCD than mothers. Children who develop OCD tend to have different patterns of symptoms than relatives with OCD, prompting genetic researchers to argue against a social learning theory of OCD transmission. Barlow (2002) has proposed that it is likely that a general anxiety vulnerability rather than a specific disorder is inherited. This may extend to a broader affective vulnerability, as Garber (2003) found that children of depressed mothers show increased risk of adult depression and anxiety disorders. The particular genetic mechanisms that contribute to pathogenesis have not been identified. A difficulty with genetic research is the challenge inherent in disentangling the influence of environmental contributions.

Family Environment

In light of the finding that OCD shows familial clustering, social learning theorists have proposed that individuals may reproduce family members' behaviors through vicarious learning (Bandura, 1977). These behaviors are then maintained by reinforcement contingencies located in the self or the environment. While genetic theorists argue that it is unlikely that OCD behaviors are socially transmitted, advocates of this approach point out that

symptoms in families are typically only assessed at a single point in time and past symptomatology is not attended to (Waters & Barrett, 2000). OCD naturally displays a waxing and waning course, with the pattern of symptoms changing over time.

An overcontrolling or overprotective parenting style may encourage anxiety development in children. Rapee (1997) posited that "excessive protection from a parent may help to provide information to the child that the world is a dangerous place and may also reduce the child's opportunities for learning otherwise" (p. 62). Children may be encouraged to avoid potentially difficult situations, reinforcing counterproductive behavioral and emotional responses, and may be more likely to perceive threat and danger in otherwise neutral situations. There is a well-documented association between an overcontrolling parenting style and anxiety in children (Barrett, Shortt, & Healy, 2002; Dumas, LaFreniere, & Serketich, 1995; Siqueland, Kendall, & Steinberg, 1996).

Expressed emotion is characterized by criticism, hostility, and/or overinvolvement. Hibbs and colleagues (1991) compared the families of children with OCD to control children and found that they were twice as likely to have a family environment high in expressed emotion. Perceived criticism is related to relapse following behavioral treatment for OCD (Renshaw, Chambless, & Steketee, 2003). Although consideration of the family environment may enhance our understanding of the cause and maintenance of OCD, attending to these factors in a clinical context may be more unhelpful than helpful. Family environment is only one of a myriad of putative OCD mechanisms, and attitudes that focus blame or negative attention on parents may lead to non-engagement in therapy and attenuate the sense of control over OCD that is often needed to get the most out of treatment.

An Immune System Response to Streptococcal Infection

Relatively recent investigations by Susan Swedo, Judith Rapoport, and their associates at the National Institute of Mental Health have revealed that a select group of children with OCD develop the disorder in the context of a strep throat infection. This condition is described by the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections). It occurs when the immune system generates antibodies in response to streptococcal bacteria, and the antibodies cross-react with the basal ganglia of a genetically vulnerable child, prompting the develop-

ment of OCD or a tic disorder (Garvey, Giedd, & Swedo, 1998; Swedo et al., 1998). The prevalence, incidence, and adulthood persistence rate of this subtype of OCD are unknown, and it has not yet been explained why the serum of 20%–40% of normal children contains similar antibodies, yet these children do not have OCD.

Brain Neuroanatomy

Brain-imaging studies have highlighted dysfunction in the neuroanatomy of the brain, particularly the orbito-frontal cortex and basal ganglia circuitry (Insel, 1992; Wise & Rapoport, 1989). Baxter, Phelps, Mazziotta, Guze, Schwartz, and Selin (1987) used position emission tomography to measure glucose metabolic rates in the brain. High glucose metabolism was observed in individuals with OCD compared to control individuals. Pharmacotherapy with serotonin-related medications can reduce glucose metabolism (Perani et al., 1995). Studies using SPECT scans have demonstrated significantly greater rates of cerebral blood flow (perfusion) in adults with OCD than in normal controls (Harris, Hoehn-Saric, Lewis, Pearlson, & Streeter, 1994; Machlin, Harris, Pearlson, Hoehn-Saric, Jeffery, & Camargo, 1991; Rubin, Villanueva-Meyer, Ananth, Trajmar, & Mena, 1992). Perfusion has been observed to decrease during medication treatment and to increase with discontinuation (Molina, Montz, Martín-Loeches, Jiménez-Vicioso, Carreras, & Rubia, 1995). Research findings on perfusion and glucose metabolism are somewhat inconsistent, probably due to differences in brain location studied, acuteness of illness, method used, and ascertainment biases.

An increased rate of OCD has been documented in several illnesses involving basal ganglia abnormalities, including Tourette's syndrome, Sydenham's chorea, Huntington's chorea, and post-encephalitic Parkinson's disease (Cummings & Cunningham, 1992; Pauls, Towbin, Leckman, Zahner, & Cohen, 1986; von Economo, 1931). Cottraux and Gérard (1998) reported that 15 of 26 studies demonstrated involvement of the basal ganglia in cases of OCD, yet the hemisphere concerned, the direction of change following treatment, and the type of functioning (hyper-functioning or hypo-functioning) varied.

Neurochemistry

There is indirect evidence that serotonin dysfunction may cause or maintain OCD (Barr, Goodman, Price, McDougle, & Charney, 1992). There are several lines of evidence to support this. Serotonin dysfunction has been observed in individuals with OCD, OCD responds

well to selective and non-selective serotonin reuptake inhibitors, and behavioral and physiological changes coincide with administration of serotonin receptor agonists. Evidence for the role of dopamine emerged from research into Tourette's syndrome. Tourette's is thought to be linked to a dysregulation in the dopaminergic neurotransmitter system due to the effectiveness of haloperidol and other dopamine antagonists in its treatment (Shapiro, Shapiro, & Eisenkraft, 1983). Tourette's frequently co-occurs with OCD (Pauls, Alsobrook, Phil, Goodman, Rasmussen, & Leckman, 1995), and a genetic relationship between the disorders has been proposed (Billet, Richter, & Kennedy, 1998). The dopaminergic system interacts with the basal ganglia, and OCD demonstrates responsiveness to medications that block the reuptake of dopamine, such as clomipramine and fluoxetine (Austin et al., 1991; Lipinski, Mallya, Zimmerman, & Pope, 1989).

Temperament

OCD is associated with personality dimensions such as neuroticism, harm avoidance, perfectionism, low novelty seeking, and low self-directedness (Frost & Steketee, 1997; Kim & Grant, 2001; Lyoo, Lee, Kim, Kong, & Kwon, 2001; Rees, Anderson, & Egan, 2006). Clinical descriptions make note of additional traits such as rigidity, inflexibility, avoidance, restraint expressing emotion, dispositional anxiety, indecisiveness, and moral rigidity. Individuals with OCD are much more likely to evidence personality disorders, which are enduring and inflexible patterns of behavior, cognition, and interpersonal functioning that pervade most aspects of everyday life. Personality disorders are regarded as clinical syndromes because they impair functioning and the pattern of symptoms deviates significantly from community norms. OCD is mostly associated with the anxious-avoidant disorders that comprise the *DSM-IV* Cluster C disorders. Obsessive-compulsive personality disorder was found in one-third of patients with OCD, compared to 5% of a general community sample, and avoidant personality disorder was 15 times more prevalent among OCD patients (15% vs. 1%; Samuels et al., 2000). Even if full syndromal criteria for a Cluster C personality disorder are not met, individuals with OCD still appear more likely to evidence the associated traits.

Cognition and Information-Processing Biases

Cognitive theory proposes that catastrophic misinterpretations of intrusive thoughts differentiate individuals with OCD from individuals without OCD. This theory is

derived from Beck's (1976) cognitive specificity hypothesis. Beck proposed that clinical anxiety results from "errors" in thinking, including the overestimation of the severity and likelihood of a feared event, and underestimation of one's personal coping resources or external factors that could alleviate the threat.

The cognitive theory is more of a maintenance model of OCD rather than an etiological model. Research shows that around 90% of individuals experience intrusive thoughts and that normal obsessions do not differ in content from obsessions in OCD (Freeston, Ladouceur, Gagnon, & Thibodeau, 1993; Niler & Beck, 1989; Rachman & de Silva, 1978; Salkovskis & Harrison, 1984). Individuals with OCD appraise intrusive thoughts in a substantively different way from non-OCD individuals. Carr (1974) developed the first cognitive model of OCD, suggesting that individuals with OCD typically overestimate the probability of unfavorable outcomes. When these high estimates are paired with a high perceived cost to the individual (e.g., harm to oneself or others), the individual may engage in behaviors or cognitive rituals to attempt to reduce the probability of the negative event.

Salkovskis (1989) proposed a very influential model concerning the inflated sense of personal responsibility frequently seen in individuals with OCD. Individuals with OCD are more likely to appraise intrusive cognitions as evidence that they will be responsible for harm to themselves or others unless they take action to avert it. Salkovskis, Richards, and Forrester (1995) defined responsibility as:

The belief that one has the power which is pivotal to bring about or prevent subjectively crucial negative outcomes. These outcomes are perceived as essential to prevent. They may be actual, that is, having consequences in the real world, and/or at a moral level. (p. 285)

An inflated responsibility appraisal perpetuates OCD symptoms by heightening the level of distress experienced by the individual in response to trigger stimuli, which increases the likelihood that compulsions will be enacted to alleviate distress (Salkovskis, 1989). There is extensive empirical support for this model (for a review, see Salkovskis & Forrester, 2002).

Rachman (1997) proposed that adults with OCD overestimate the importance of intrusive thoughts. An individual with OCD is more likely to believe that negative intrusive thoughts indicate something significant about him or her (e.g., "I am weird, deviant, horrible") or that the thoughts convey highly important information that must be attended to (Thordarson & Shafran,

2002). The individual may overemphasize the importance of intrusive thoughts due to the frequency of their occurrence in conscious awareness or as a result of the content of the thought. Catastrophic misinterpretations lead to distress, increased obsessions, and the utilization of neutralization and thought suppression strategies. Notably, thought suppression strategies are futile and have the paradoxical effect of increasing the frequency of the occurrence of intrusive thoughts. This is referred to as the "white bear" effect based upon experiments by Wegner, Schneider, Carter, and White (1987).

Individuals with anxiety disorders tend to have a greater intolerance of uncertainty, finding this cognitive state aversive and distressing. Adopting Kruglansky's definition of cognitive closure, Mancini, D'Olimpio, Del Genio, Didonna, and Prunetta (2002) described intolerance of uncertainty as the desire for "*an* answer on a given topic, *any* answer . . . compared to confusion and ambiguity" (Kruglansky, 1990, p. 337). Freeston, Rheume, Letarte, Dugas, and Ladouceur (1994) regarded intolerance of uncertainty as a cognitive bias that affects how an individual appraised and responded cognitively, affectively, and behaviorally, to uncertain situations. Although Mancini et al.'s conceptualization emphasizes the need for cognitive closure, recent research has shown that intolerance of uncertainty may be more related to low confidence in one's memory or cognitive abilities. Individuals with OCD desire more vivid memories (Constans, Foa, Franklin, & Mathews, 1995) and have less confidence in their memory than non-anxious individuals (Hermans, Martens, De Cort, Pieters, & Eelen, 2003). No differences in actual memory function are evident (Hermans et al., 2003). This discrepancy between perceived ability to remember and desired ability may result in difficulty tolerating uncertainty (Tolin, Abramowitz, Brigidi, & Foa, 2003). Individuals with poor perceived memory or cognitive confidence are likely to exhibit greater pathological doubting and greater intolerance of uncertainty.

Rachman (1993) believed that individuals with OCD may fuse thoughts and actions. Thought-action fusion is a form of metacognitive processing. Thought-action fusion is:

the belief that (one's) specific intrusive thoughts can directly influence the relevant external event and/or the belief that having these intrusive thoughts is morally equivalent to carrying out a prohibited action. (Rachman & Shafran, 1999, p. 80)

Probability or likelihood thought-action fusion refers to the belief that thoughts can directly influence external

environmental stimuli. Individuals with this type of cognitive distortion fear that thinking about a dreaded event, such as a relative dying in a car accident, increases the likelihood that the event will occur. Morality-thought-action fusion refers to the belief that having an intrusive thought is morally equivalent to performing the event action that one is thinking about. Individuals may believe that intrusive thoughts about performing sexual acts on a minor, or stabbing a friend, are as repulsive and evil as actually performed these acts. These irrational beliefs have been documented for over a century. Maudsley (1895) wrote that a patient like this “is constrained to think of doing an indecent act and is in fright lest he should someday do it” (p. 184). Bleuler (1934) noted that “patients also fear that they might destroy their beloved ones through a thought (‘omnipotence of thought’)” (p. 561). This cognitive appraisal style influences the development of clinically significant obsessions by increasing the frequency of occurrence of intrusive thoughts and a person’s corresponding level of distress (Berle & Starcevic, 2005).

Wells and Matthews (1994) proposed a prototypal metacognitive model of emotional disorders. They incorporated aspects of earlier cognitive theories into their model but added the additional tier of metacognition. They proposed that unhelpful beliefs about cognitions and cognitive processes are central to the maintenance of emotional disorders, including OCD. For instance, individuals with OCD are more likely to believe that thinking about an event is related to the probability of the event’s occurrence (thought-action fusion). When an intrusive, ego-dystonic cognition occurs, individuals with thought-action fusion beliefs are more likely to overestimate the probability of harm, to experience distress, and to engage in neutralizing behaviors. Individuals with OCD are more likely to believe that they need to control their thoughts. Thought control strategies such as suppression often have the paradoxical consequence of increasing the frequency of intrusive thoughts. Individuals with emotional disorders are more likely to evidence unhelpful metacognitive beliefs.

Cognitive-Behavioral Model of OCD Maintenance

The cognitive maintenance model proposed above has greater explanatory power when paired with behavioral maintaining processes. The paradigm of the vicious circle applies, whereby a particular event or internal experience is interpreted by the individual with OCD in a way that leads to increased distress (e.g., thinking that

one has left the front door unlocked and then worrying that someone may break into the house). Performance of a compulsion to achieve neutralization of the obsession results in a temporary reduction in anxiety (e.g., returning home to check that the door is locked). This anxiety relief is negatively reinforcing and increases the likelihood that the compulsion will be performed in future recurrences of the obsessions. The obsessions are likely to be repeated because unhelpful information-processing biases maintain them. Symptoms are maintained not only through negative reinforcement but also through behavioral avoidance of anxiety triggers (e.g., not leaving the house), which ultimately prevents anxiety habituation and disconfirmation of the unhelpful beliefs. The CBT model is the best-established maintenance model of OCD, and cognitive-behavioral interventions are directly derived from this model.

EVIDENCE-BASED MANAGEMENT OF OBSESSIVE-COMPULSIVE DISORDER

Until the mid-1960s, OCD was considered a treatment refractory condition (Foa et al., 1998). Prior to then, psychodynamic psychotherapy was used to treat individuals with this disorder. The National Institute for Health and Clinical Excellence (NICE; 2005) guidelines represent the most comprehensive review of all OCD treatments to date and indicate that there is no evidence for the efficacy or effectiveness of psychodynamic psychotherapy, which perhaps explains why OCD was considered treatment refractory until the development of alternative therapies. Since then, CBT and pharmacotherapy have emerged as the leading treatments for this disorder. Both treatments have consistently shown superior results to placebo and other control conditions in randomized treatment studies among adults and children. It is now clear that OCD can be effectively treated and often within a brief therapeutic period (12 to 20 weeks).

The NICE guidelines advocate a stepped-care management approach to treating OCD. This was informed by a desire to utilize the least intrusive and least expensive treatment services necessary to promote clinical change. This tiered approach to service allocation is becoming increasingly popular as managed care encroaches on health practices and systems. The stepped-care approach to managing OCD in children and adults, adapted from the recommendations of the NICE guidelines, is shown in Figure 16.1. It is important for clinicians—regardless of their particular theoretical or professional orientation—to maintain knowledge of

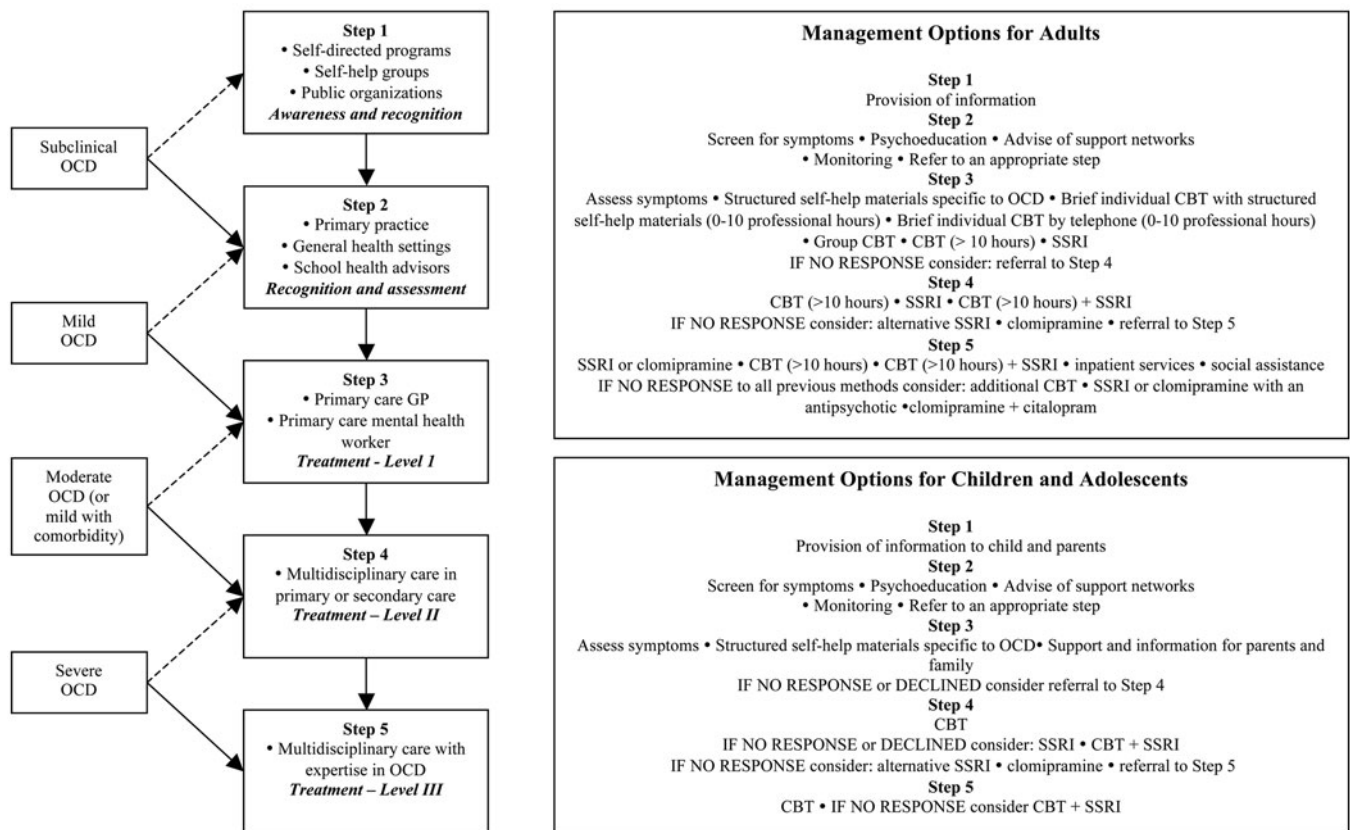

Figure 16.1 A stepped-care model for the management of OCD in adults, children, and adolescents.

evidence-based treatment approaches so that individuals with OCD receive accurate, consistent information and are encouraged in the direction of best care.

Cognitive-Behavioral Therapy

CBT is advocated as a first-line treatment approach for children with OCD, and for adolescents and adults with mild to moderate OCD. The combined cognitive-behavioral approach to treating OCD incorporates the components of behavior therapy and cognitive therapy to address the problem behaviors and erroneous thinking that maintain the disorder. Behavioral therapy for OCD primarily utilizes the technique of ERP. ERP involves graduated contact with a feared stimulus, while the client abstains from engaging in the usual rituals or avoidance behaviors. For example, a client with concerns about germs must not only touch objects perceived to have germs on them but also refrain from ritualized washing until his or her anxiety diminishes. With re-

peated exposures, anxiety decreases until eventually it is no longer experienced and habituation is achieved. The cognitive therapy component of CBT allows the therapist to address the faulty cognitions that lead to distress and anxiety in the context of trigger stimuli. Cognitive therapy applications may involve addressing estimations of danger through probability testing, examination of the nature of thought-action fusion with the client, and exploration of the exaggerated sense of responsibility and pathological doubt often seen in clients with OCD.

Although practice guidelines clarify first-line and evidence-based treatment for OCD, surveys suggest that mental health workers are typically not employing or are misapplying evidence-based treatments, including CBT (Gallant, Storch, Valderhaug, & Geffken, 2007; Valderhaug, Götestam, & Larsson, 2004). In a recent survey of child school psychologists, 82% reported that they were much or very much inclined to use evidence-based treatments, yet less than 7% reported regularly

applying ERP to cases of OCD (Gallant et al., 2007). Of those who were inclined to use of evidence-based treatments, approximately 63% stated that they rarely or never used ERP elements in practice with OCD.

What then are mental health workers using to treat OCD? The high rate of knowledge advance and impressive cross-disciplinary developments means that knowledge can become significantly outdated fairly quickly. Clinicians may be using CBT or other strategies that are not helpful to their clients and that do not map on to current models of disorder maintenance. In order to understand the intricacies of modern-day CBT for OCD, it is useful to have an understanding of the historical development of the treatment. Many early techniques have been shown to do more harm than good yet continue to be used by those failing to stay abreast of important developments in treatment research.

Historical to Modern Day Practice of CBT for OCD

In this section we will describe the development of CBT, detailing the evidence supporting specific applications, and outlining strategies that have been disproved and are not supported by evidence. We will arrive at an understanding of CBT for OCD in its modern form.

The behavioral approach was the first mainstream therapeutic alternative to psychodynamic therapy. This approach involved graduated deliberate exposure to feared stimuli with the prevention of the response typically invoked by the individual to reduce associated distress. Graduated exposure for anxiety disorders was first described by Wolpe (1958), who utilized systematic desensitization procedures with a range of clients with obsessive-compulsive and phobic symptomatology. Wolpe initially instructed clients in progressive muscle relaxation techniques. The therapist and client then developed a list, or hierarchy, of anxiety-provoking stimulus situations that were ranked according to the amount of disturbance each situation would evoke. In session, once relaxed, the client was asked to imagine and sometimes describe a feared situation from the hierarchy, working from the least to most disturbing situation over a number of treatment sessions. Wolpe proposed that over time the magnitude of anxiety experienced by the individual would lessen as the relaxation opposed and inhibited the anxious response. Several cases were presented to illustrate that the process of systematic desensitization by reciprocal inhibition was capable of reducing the anxiety associated with a large range of stimuli. However, the results of this process,

when applied to OCD, have since been described as unpredictable and unstable (Tallis, 1995).

Meyer (1966) proposed that systematic desensitization by reciprocal inhibition, as described by Wolpe, was lacking in several ways. Meyer emphasized the importance of controlling the symptoms not only during but also in between treatment sessions. Yet he recognized the great difficulty of preventing the reoccurrence of persistent rituals between treatment sessions due to their frequency and the inability of the individual to withdraw from the anxiety-inducing obsessions. Furthermore, Meyer recognized that systematic desensitization by reciprocal inhibition may not provide opportunities to address the numerous concerns and types of rituals often seen in chronic cases of OCD. Meyer therefore described a treatment approach incorporating exposure to a feared situation in which the individual is persuaded or forced to remain without undertaking his or her usual rituals. This treatment approach is today referred to as ERP.

Meyer proposed that the purpose of ERP is twofold, in that it allows the individual to realize that the persistent non-performance of rituals does not lead to the immediate experience of unrestrained anxiety and that the individual's expectations of disastrous consequences are not likely to be fulfilled. Meyer explored this formulation using intensive ERP with two treatment refractory patients with obsessive-compulsive symptoms. Patients were exposed to feared activities related to their obsessions (e.g., the patient was made to touch items believed to be "dirty"), and strict control over their ability to engage in rituals was maintained (e.g., the bathroom taps were turned off, the individual was continuously monitored by nursing staff). Persuasion, reassurance, encouragement, and relaxation were used to prevent the individual from engaging in rituals. Favorable treatment responses were noted for both patients.

Later studies by Meyer and colleagues (Meyer & Levy, 1973; Meyer, Levy, & Schnurer, 1974) indicated favorable outcomes for ERP programs; however, two techniques utilized in these studies may have attenuated the results. First, the intensive 24-hour supervision typical of Meyer's treatment may be likened to reassurance provision. Rachman and Shafran (1998) assert that patients may seek reassurance that something did or did not happen, or that something bad will not happen, or that they have done something correctly, and that this reassurance seeking may equate to a compulsive behavior. Furthermore, the presence of another individual has been known to modify an individual's anxiety levels when exposed to a feared stimulus (Roper & Rachman, 1976). Therefore, later studies have emphasized

that reassurance must not be provided to individuals participating in treatment, and that individuals should be encouraged to partake in self-exposure as a homework exercise (Foa et al., 1998). Second, Foa and Kozak (1986) have proposed that anxiety must be experienced in order for emotional processing to occur and that the relaxation techniques employed in earlier studies may impair the efficacy of exposure exercises by allowing the individual to avoid the experience of anxiety. Therefore, relaxation is not currently utilized in the treatment of OCD.

Over the past few decades, the efficacy of ERP has continued to be evaluated in a range of randomized and controlled treatment trials. In a review of 273 clients with OCD treated by ERP, Foa, Steketee, and Ozarow (1985) found a symptom reduction of at least 70% in 51% of the clients treated, reductions of between 31% and 69% for 39% of clients treated, and treatment failure (i.e., less than 30% symptom reduction) in 10% of clients. This finding of high rates of symptom reduction has been replicated in other studies of ERP (e.g., Kozak, Foa, & Steketee, 1988; Lindsay, Crino, & Andrews, 1997) and supported in subsequent meta-analyses (e.g., Abramowitz, 1998). More recently, Eddy, Dutra, Bradley, and Westen (2004) conducted a meta-analysis of OCD treatment trials and found that ERP alone or in addition to either cognitive therapy or pharmacotherapy may be more effective than cognitive therapy or pharmacotherapy alone as treatment for the disorder. A long-term follow-up study has indicated that the majority of individuals (i.e., 78%) who make treatment gains are able to retain them over longer periods of 1–6 years (O'Sullivan, Noshirvani, Marks, Montiero, & Lelliot, 1991).

Even before the advent of cognitive theory and therapy for OCD, it was believed that the efficacy of behavior therapy for OCD may, in part, be attributable to changes at the cognitive level. Foa and Kozak (1986) argued that the efficacy of ERP was, in fact, moderated by the disconfirmation of dysfunctional thinking and erroneous beliefs. Cognitive therapy, which specifically seeks to bring about helpful change in one's thoughts or thinking styles, was thus proposed as a useful, and perhaps even stand-alone, strategy in the treatment of the disorder. Cognitive therapy was largely developed and refined by Aaron Beck (1967, 1976), who proposed that emotional disorders are the consequence of distorted thinking or unrealistic cognitive appraisals of life events. Cognitive therapy usually incorporates a demonstration of the link between thoughts, affect, and/or behaviors; the identification of erroneous thinking styles; and instruction in self-questioning methods (and

sometimes behavioral experimentation) to assess the validity of the original erroneous thoughts.

The efficacy of cognitive procedures has been explored in a range of treatment studies with individuals with OCD. Emmelkamp, van der Helm, van Zanten, and Plochg (1980) compared ERP to a combined self-instruction training and ERP approach. The self-instruction training, as proposed by Meichenbaum (1975), involved asking the patient to cognitively rehearse preparing for, confronting, and coping with an imagined anxiety-provoking situation, while also applying relaxation techniques and practicing productive self-statements. This process was then directly followed by in-vivo exposure. The results indicated that both ERP alone and the combined approach led to clinical and statistically significant improvements, yet the addition of the self-instruction training did not enhance the effects of the ERP.

Emmelkamp and colleagues (Emmelkamp & Beens, 1991; Emmelkamp, Visser, & Hoekstra, 1988) furthered the exploration of cognitive techniques in the treatment of OCD by examining the use of rational emotive therapy (Ellis, 1962). Although developed independently, rational emotive therapy and Beck's cognitive therapy are conceptually similar in that they both stress the role of faulty or irrational thinking in the development of emotional disorders and the modification of such thinking in treatment. Emmelkamp and colleagues found that rational emotive therapy as a stand-alone treatment, or in combination with ERP is able to bring about significant improvements in OCD symptoms but does not differ significantly from the results of ERP treatment alone.

The finding that cognitive therapy can bring about significant symptom change but does not improve the treatment efficacy for OCD has been consistently described in the earlier treatment literature (James & Blackburn, 1995). Yet several problems with early studies concerning cognitive therapy for OCD are noted in the literature. James and Blackburn point out that numerous earlier studies labeled thought stopping a cognitive therapy technique. Including thought stopping procedures within the cognitive framework may have attenuated treatment results for two reasons. First, thought stopping has been argued to be an aversive behavioral, rather than cognitive, technique. Second, thought stopping has displayed questionable efficacy as a treatment for OCD (Stern, 1978; Stern, Lipsedge, & Marks, 1973). McLean and colleagues (2001) have further demonstrated that few early studies addressed faulty appraisals thought to be particularly relevant to OCD. With advances in the cognitive conceptualization of OCD over the past decade, it has been proposed that

cognitive therapy treatment studies incorporate components that address faulty estimations of danger (van Oppen & Arntz, 1994), elevated responsibility appraisals (Salkovskis, 1985), and thought-action fusion beliefs (Shafran et al., 1996).

Van Oppen, de Haan, van Balkom, Spinhoven, Hoogduin, and van Dyck (1995) conducted the first controlled trial evaluating cognitive therapy as treatment for OCD as proposed by Beck (1976) and Salkovskis (1985). Seventy-one patients were randomly assigned to 16 sessions of either cognitive therapy or self-controlled exposure in vivo with response prevention. In the cognitive therapy condition, particular attention was paid to addressing inflated estimates of personal responsibility and overestimations of danger. Techniques utilized included Socratic questioning and the recording and challenging of thoughts in a diary for homework. The authors reported that both treatments led to statistically as well as clinically significant improvements in OCD symptomatology, with a significantly higher number being rated as "recovered" on measures of OCD symptomatology in the cognitive therapy condition. While these findings led the authors to suggest that cognitive therapy may be a superior strategy in the treatment of OCD, it is important to recognize that behavioral experiments were conducted during 10 of the 16 sessions in the cognitive therapy condition. Although different rationales are used for behavioral experiments and ERP, the very nature of the two can certainly be likened in that behavioral experiments often involve anxiety-provoking situations in which the usual compulsive response is altered to test an alternative hypothesis. Caution is required in interpreting the results of this treatment study.

Cottraux and colleagues (2001) furthered the exploration of cognitive versus behavioral therapy in the treatment of OCD in a randomized controlled trial. Thirty-five outpatients were randomly assigned to either cognitive therapy or an intensive behavioral therapy program over a 16-week period. Cognitive therapy components included the elicitation of intrusive and automatic thoughts; Socratic discussions; and elicitation and discussions of dysfunctional danger and responsibility schemas, magical ideation, and thought-action fusion. Given that a significant component of OCD is the presence of intrusive, unwanted thoughts, exploring thought-action fusion is of particular benefit to the treatment of obsessional problems, as it allows for exploration of the meaning the individual attaches to the intrusive thought. This study, unlike the van Oppen et al. (1995) study, was therefore able to include individuals with primarily obsessional problems. The re-

sults indicated that cognitive and behavioral therapies had similar outcomes for OCD symptoms, but that cognitive therapy had specific effects on depression symptoms and on dysfunctional interpretations of intrusive thoughts that behavioral therapy did not have. The finding that the cognitive treatment modified scores on a depression inventory may be fruitful given the large numbers of individuals who present with comorbid depression and OCD. Current estimates indicate that between 20% and 40% of individuals with OCD also have major depression (Denys et al., 2004; Steketee, Eisen, Dyck, Warshaw, & Rasmussen, 1999; Tükel et al., 2002). Unfortunately, individuals with major depression were excluded from this study, thus limiting the generalizability of the findings. Further studies examining the specific effects of cognitive therapy on comorbid depression are required. There is a need to evaluate suggestions by Vogel, Stiles, and Götestam (2004) that the addition of a cognitive component addressing the range of other comorbid symptoms experienced by the individual with OCD may reduce the high dropout rates typically noted in standardized behavioral therapy.

Eddy and associates (2004) evaluated the relative efficacy of CBT and ERP in a meta-analysis of 15 clinical trials. The treatment results of 16 ERP conditions and 4 CBT conditions were compared to establish mean pre- to post-treatment effect sizes of 1.53 and 1.39 for ERP and CBT, respectively. They concluded that the behaviorally, as opposed to cognitively, oriented psychotherapies tend to be more efficacious. These conclusions should be regarded with caution given that far fewer cases were used to determine the effect size for the CBT condition, no improvement and recovery rates were identified for the CBT condition for comparison to ERP, methodological differences in the studies could account for discrepancies in the mean effect sizes (e.g., the use of extreme exclusion criteria in the Fals-Stewart, Marks, and Schafer, 1993, ERP study not noted in other studies), and the median effect sizes of 1.32 and 1.27 for ERP and CBT respectively were somewhat more comparable.

Salkovskis et al. (1998) suggested that cognitive therapy may offer an alternative approach to the conceptualization and treatment of OCD and could compensate for shortcomings of the behavioral approach. They stated that even when programs involve high levels of ERP, there is considerable room for improvement in terms of treatment outcomes. Furthermore, they asserted that behavior therapy alone does not provide for a differential conceptualization for OCD from other anxiety disorders, nor does behavior therapy promote understanding of the modifying effect that the presence

of the therapist or another trusted individual may have on the individual's anxiety levels (Roper & Rachman, 1976). While the cognitive model may address some of the limitations of the behavioral approach, there is little evidence to date of its efficacy as a stand-alone treatment. The NICE guidelines and the Expert Consensus Guidelines on the treatment of OCD (March, Frances, Carpenter, & Kahn, 1997) therefore recommend the combined cognitive-behavioral approach as the first line of treatment for OCD.

CBT for Children and Adolescents

The CBT approach has been evaluated in child and adolescent as well as adult samples and yields similar strong evidence of efficacy. Over 60 studies have examined either behavior therapy, cognitive therapy, or CBT for pediatric OCD, with the majority favoring a CBT approach. An important development to the clinical dissemination of CBT among young people has been the manualization of treatment by March and Mulle (1998). The program contains core components of adult CBT programs, such as psychoeducation, graded ERP, cognitive therapy, and relapse prevention, yet therapeutic content is delivered in a developmentally appropriate manner. For instance, the obsession or compulsion might be given creative names such as "Germy" with younger children to promote externalization of symptoms and to enhance motivation to "get rid of Germy." Most pediatric CBT programs usually involve 12–20 hour-long sessions delivered weekly. Himle (2003) conducted a trial with 10 children comparing group CBT to a placebo control. Children receiving CBT showed an average 40% reduction in symptoms at post-treatment, while children in the placebo group showed an average 22% reduction. An adaptation to the original protocol emphasizing a family-based approach was evaluated in a randomized controlled trial (RCT) by Barrett, Healy-Farrell, and March (2004). Seventy-seven children and families were assigned to a 14-week package of individual or group CBT. The program involved three joint child, parent, and sibling sessions, and the remaining sessions comprised concurrently scheduled child and parent/sibling sessions. Parent and sibling sessions involved support and psychoeducation and strategies to target family accommodation of symptoms, which is an important hypothesized mechanism of change. Both individual and group CBT had a significant impact on children's OCD symptoms (65% and 61% reduction respectively, vs. a 5% increase among the wait-list control group). At 3-month follow-up, 82% of individually treated and 76% of group-treated children were diagnosis free. At 12 months the corresponding rates were

70% for individual CBT participants and 84% for group CBT participants, suggesting that the treatment effect is durable (Barrett, Farrell, Dadds, & Boulter, 2005).

The most influential and methodologically impressive study to date is the Pediatric Obsessive-Compulsive Treatment Study (Pediatric OCD Treatment Study Team, 2004). The trial employed a multisite randomized placebo-controlled design and involved academic clinical centers at Duke University, Brown University, and the University of Pennsylvania. Child outpatients with OCD ages 7–17 years were randomly assigned to a 12-week course of CBT, the selective serotonin reuptake inhibitor (SSRI) sertraline, combination CBT and sertraline, or pill placebo. Over 85% of individuals completed treatment, and dropout was equivalent across the active treatment conditions. Outcomes were compared at baseline and weeks 4, 8, and 12. All treatments significantly reduced the severity of OCD symptoms, with average scores in all groups decreasing from the severe threshold to the mild threshold in the three treatment conditions, and to the moderate threshold in the placebo condition. Combined treatment did not differ in effectiveness from CBT alone but was superior to sertraline and pill placebo. Treatment effect sizes were 1.4 for combined treatment, 1.0 for CBT alone, and .07 for sertraline. When remission was defined as a CY-BOCS score less than or equal to 10, remission rates were 54% for combined treatment, 39% for CBT, 21% for sertraline, and 4% for placebo. A strength of the study was the inclusion of a clinically representative sample, as 80% of the sample had at least one comorbid Axis I disorder and 63% had multiple comorbidities. The POTS results attest to the importance of a shared framework for understanding OCD among physicians, psychiatrists, and clinical mental health professionals. Not all those treated with a first-line treatment reach remission criteria, and second-line treatments may be pharmacologically or psychologically based, lending credence to the utility of an integrated approach to disorder conceptualization and management. Favorable results for CBT continue to accrue (e.g. Bolton & Perrin, 2008). A meta-analysis of pediatric CBT RCTs revealed an average treatment effect of 1.45 (95% CI: .68, 2.22; Watson & Rees, 2008). One RCT at an expert CBT site in Australia was observed to produce a very strong treatment effect, yet a large treatment effect was still noted with exclusion of this trial.

Pharmacotherapy

Medication is considered a valuable treatment in the stepped-care model of OCD (see Figure 16.1). Manipulation of the serotonin system has been identified as a means by which obsessive-compulsive symptoma-

tology can be altered, and despite our unclear understanding of the role of serotonin in the development of OCD, particular antidepressant medications have been shown to be effective in reducing OCD symptom severity. Most commonly, these have consisted of the serotonin reuptake inhibitor (SRI) clomipramine, or one of the SSRIs, such as fluoxetine, fluvoxamine, sertraline, paroxetine, or citalopram. Pharmacotherapy treatment generally spans 8–16 weeks, although some trials have indicated that an extension of treatment can produce response in some non-responders and should be considered. It may take 2–3 months for individuals to experience a response to pharmacotherapy, so it is important to persist with treatment for this duration before switching to a higher dose, alternative agents, or augmentation strategies. Medication can be particularly useful for adults with moderate OCD, for individuals who do not wish to engage in psychotherapy, for those with comorbid anxiety and mood symptomatology, or for those with insufficient access to CBT. It is important to note that the Expert Consensus Guidelines (March et al., 1997) do not recommend medication alone in the treatment of OCD and only recommend medication (SRI/SSRIs) in combination with CBT for adult clients who are seen as having severe OCD.

An earlier review of four large multicenter, placebo-controlled trials of these medications indicated that 60% of adults treated with clomipramine were rated as much or very much improved, which was significantly greater than the percentages reported for fluvoxamine (43%), fluoxetine (38%), and sertraline (39%; Greist, Jefferson, Kobak, Katzelnick, & Serlin, 1995). This review reported effect sizes for these medications showing clomipramine (1.48) to be significantly more effective than fluvoxamine (0.50), fluoxetine (0.69), and sertraline (0.35). However, experts in the treatment of OCD have tended not to endorse clomipramine as the first-line medication choice for patients (March et al., 1997), recognizing that significant side effects associated with this medication may lead to tolerability issues and subsequent dropout. This was supported by the NICE guidelines, which examined data from 1,019 patients treated with medications and indicated that although SSRIs and clomipramine are both efficacious treatments, there is a great likelihood of people discontinuing clomipramine due to adverse effects.

Clomipramine, fluvoxamine, sertraline, fluoxetine, and paroxetine have demonstrated efficacy in randomized, placebo-controlled trials for children. In Watson and Rees's (2008) meta-analytic review of pediatric OCD RCTs, pooled analyses showed that the effect size was .48 for any pharmacotherapy (10 RCTs), .85 for clomipramine (2 RCTs), .51 for fluoxetine (3 RCTs), .47 for ser-

traline (2 RCTs), .44 for paroxetine (2 RCTs), and .31 for fluvoxamine (1 RCTs). All effect sizes were significant except for that of fluvoxamine. Clomipramine produced a 37%–50% reduction in symptoms. Percent reductions among the SSRI studies were 39%–44% for fluoxetine, 36%–38% for paroxetine, 29%–30% for sertraline, and 24% for fluvoxamine. Congruent with adult recommendations, clomipramine is regarded as a second-line agent to the SSRIs due to the more adverse side effect profile.

Significant side effects that may lead to treatment noncompliance or discontinuation are but one of several considerations affecting the advocacy of medication use for OCD. Side effects commonly noted to accompany the use of SSRIs include nausea, tremor, appetite changes, headaches, and dizziness. Reported side effects of clomipramine are palpitations, sweating, tremor, drowsiness, weight gain, an increased seizure risk, and arrhythmias. As may be seen in the rates above, between 40% and 60% of individuals do not respond to adequate treatment trials and thus require alternative treatments. Furthermore, OCD is associated with a large range of comorbid disorders, some of which warrant caution when SRI/SSRIs are being used. For example, serotonin-based medications may lead to a worsening of panic disorder symptoms and can trigger mania in those predisposed to bipolar disorder (Kaplan & Hollander, 2003). There has been some concern that psychiatric medication usage has been insufficiently monitored among children and that the effects at such a precocious and important period of biological and cognitive development are poorly understood. In recent years there has been media attention and alarm accompanying the claim that SSRIs are associated with an increased risk of suicidality. A review of all RCTs of SSRIs among children published between 1988 and 2006 showed that there was a significant overall increased risk of treatment-emergent suicidal attempts and ideation compared to placebo (4% vs. 2%; Hammad, Laughren, & Racoosin, 2006). Of the 4,582 patients included in the review, no child completed suicide. An independent risk-benefit review of 5,310 children revealed that the potential benefits of SSRI treatment are much greater than the risks (Bridge et al., 2007). An evaluation of the relative benefits and risks, and close monitoring of suicidal thoughts and behaviors (particularly in the first 4 months of SSRI treatment), is necessary to consider in the management of child emotional problems with SSRIs. For adults, the evidence is inconclusive regarding the association between SSRIs and increased suicidality; however, it has been suggested that SSRI use may cause an increased risk in patients already experiencing depression (National Institute for Health and Clinical Excellence, 2006).

Finally, for those individuals who discontinue medication for OCD either due to an inability to tolerate the side effects or due to clinically significant improvements that suggest successful pharmacological treatment of the OCD, two further difficulties arise. First, SRI/SSRI medication discontinuation, especially rapid discontinuation, has been associated with the onset of a number of aversive and sometimes severe reactions. Lengthy gradual tapering of medication is therefore sometimes required before another drug can be trialed. Second, of those who do respond favorably to medications, between 65% and 90% relapse upon medication discontinuation (Rasmussen & Eisen, 1997). These findings have been noted for children, with one study evaluating 54 children 2–7 years old after they received 5 weeks of clomipramine treatment for OCD (Leonard, Swedo, Lenane, Rettew, Hamburger, Bartko, & Rapoport, 1993). The mean age of the participants at follow-up was 17 years. At follow-up, 43% of participants met criteria for clinical OCD and 18% were classified as subclinical OCD.

Combination Treatment

Combined pharmacotherapy and CBT treatment is indicated as a first-line treatment for adults and adolescents with moderate to severe OCD by the Expert Consensus and NICE guidelines. An integrated treatment utilizing psychological and biological interventions has the advantage of targeting a wider range of OCD-maintaining mechanisms and may confer a clear advantage when response to monotherapy or a less intensive form of therapy would likely be insufficient. The Pediatric OCD Treatment Study trial is the only head-to-head comparison to date of monotherapy medication and monotherapy CBT and combined CBT/pharmacotherapy treatment in children (Pediatric OCD Treatment Study Team, 2004). This trial showed that CBT and combination treatment were the most efficacious, with no significant differences in average OCD severity between the two groups at post-treatment. Similarly, a small number of trials with adults have indicated that combination treatment may lead to greater symptom improvement than CBT or SSRI treatment alone (National Institute for Health and Clinical Excellence, 2006).

CLINICAL PRACTICE

Treatment of OCD clients in the real world is a rewarding experience. An understanding of the contemporary diagnosis, assessment methods, causal and maintaining

models, and key recommendations of evidence-based research and clinical guidelines greatly facilitates the outcome of treatment. The development of individualized patient formulations is an essential step in treatment planning. All formulations should consider the salient predisposing, precipitating, and perpetuating factors relevant to the patient who has been assessed. The formulation will highlight the most important factors that are contributing to symptom maintenance. These identified factors then become the target of intervention. For example, if an individualized formulation reveals that the behavioral act of repetitive reassurance seeking from doctors and family members is maintaining OCD, it must be addressed in treatment. Once the clinician has established the individualized formulation, it is important that he or she feed this back to the patient so that the patient has a clear understanding of the factors contributing to and maintaining the symptoms.

A useful means of illustrating the translation of efficacy research into real-world practice is case examples that highlight the process of treatment. In what follows, we discuss an adult and child with OCD who were referred for specialist treatment, illuminating key processes that clinicians can plan for and engage in to ensure thorough and effective assessment and treatment.

Adult Case

Patrick was a 46-year-old-male who was working full-time as an accountant and was married with two children. He was referred by his general practitioner for assistance with acute anxiety symptoms that first presented 12 months prior. Patrick's symptoms concerned two main areas: (1) fear that he might bite off his own tongue and (2) fear of losing control and stabbing his wife and children. Patrick was performing the ritualistic behavior of holding his tongue between his teeth in response to his tongue-biting thoughts. Patrick reported some suicidal ideation but indicated he would not follow through because of the responsibility he felt for his two daughters. He had begun taking the prescribed SSRI fluoxetine 10 months earlier to manage his low mood and intrusive thoughts. Although he reported that medication had helped, he was still experiencing significant symptoms that were interfering with his life. These symptoms had not been responsive to a prescribed increase in the medication dosage initiated 4 months prior.

Background to the Presenting Problem

Patrick was the eldest of four brothers and was raised in what he described as a "turbulent" family atmosphere.

His father was an alcoholic and there were frequent fights between his mother and father. Patrick explained that he was often drawn into the arguments and remembers feeling “terrified” of his father, who was a powerful and moody man. His mother relied heavily on Patrick to help her through her marital difficulties and would often ask him to sleep in the marital bed with her so that she could talk late into the night about her problems. Patrick reported that although his mother was not officially diagnosed, he believes that she may have had clinical depression. Patrick also recalled that both parents were unable to express warmth or love. Patrick recalled being a “nervy child” who worried about doing well at school. He followed rules and was always very cooperative. He did not have much experience testing out potentially dangerous situations for himself, since his mother was overprotective and shielded him and his brothers from anything that she saw as potentially harmful with instructions such as “Be careful, you could get hurt!” Patrick married at around age 27 and has two daughters ages 18 and 20 years. Patrick was recently promoted at work and admitted to feeling more stressed and preoccupied with doing a perfect job.

Diagnosis and Assessment

Patrick attended a clinical interview, during which the ADIS-IV was administered (see Exhibit 16.2).

16.2 | Patrick's DSM Multiaxial Evaluation

Axis I	300.3	Obsessive-compulsive disorder
	296.31	Major depressive disorder, recurrent
Axis II		Obsessive and avoidant personality traits (no diagnosis)
Axis III		None
Axis IV		None
Axis V		Global assessment of functioning = 61, current

Formulation

Predisposing factors. Biological factors appear to be relevant to the development of Patrick's difficulties. Patrick described himself as always having been an anxious child. It is likely that his father had elevated levels of stress and used alcohol as a means of self-medication. Research has shown that children of alcoholics have a higher than usual likelihood of developing anxiety disorders (Schuckit & Hesselbrock, 2004). McLaren and Crowe (2003) suggest that people who develop OCD have a biological predisposition to react strongly to stress and that this reaction takes the form of intrusive, distressing thoughts, which further increase stress. Children of depressed mothers demonstrate an increased risk of adult depression and anxiety disorders (Garber, 2003).

Early-life messages and experiences can shape our vulnerability to illness. Children who are given too much responsibility for their developmental stage (parentified) are at a greater risk of developing an exaggerated sense of responsibility as adults. Patrick was clearly put into a position of responsibility by his mother, who would ask him to comfort her and support her emotionally. An excessive sense of responsibility has been identified as a major cognitive schema in OCD (Foa, Amir, Bogert, Molnar & Przeworski, 2001).

Childhood temperament is related to the development of adult anxiety disorders (Pérez-Edgar & Fox, 2005). Patrick described himself as always having been a “nervy child” who “slept poorly and worried about things such as school reports.” Patrick also identified himself as a person who had always been concerned about striving to meet very high standards and worried excessively if this was not achieved. Perfectionists, who expect too much from themselves or others, tend to be at greater risk of OCD and depression (Hewitt & Dyck, 1986).

Precipitating factors. A distal trigger for OCD may have been the affair that Patrick's wife had 2 years earlier. He blamed himself for the affair, as he was “not there for her.” This affair is likely to have caused significant stress and disruption to their interpersonal relationship. A proximal trigger appears to be Patrick's promotion and his “preoccupation” with “doing a good job,” which caused him a great deal of stress.

Perpetuating factors. Patrick experienced significant physiological anxiety symptoms in response to his intrusive thoughts. He misinterpreted these sensations as further evidence that he was losing control of his mind, body, and behavior. Patrick engaged in a number of unhelpful thinking styles or cognitive distortions that

maintained his anxiety. Primarily, Patrick engaged in unhelpful metacognitions (thoughts about thoughts). He ascribed inflated importance to the occurrence of thoughts (over-importance of thought). As such he was unable to recognize that the intrusive thoughts he was experiencing were not facts but rather part of the normal landscape of cognition. When he experienced one of his unwanted intrusive thoughts, he engaged with the thought and attempted to either push it away or reason with it. The failure of his attempts at thought control resulted in an increased frequency of the thoughts and then further (unsuccessful) efforts to push them away.

Patrick evidenced thought-fusion beliefs. He believed that having unwanted thoughts (e.g., hurting his family) meant that there was a high risk of the aversive events happening in reality (likelihood subtype of thought-action fusion). Another variation of thought-action fusion is the moral subtype. Patrick showed evidence of this in his belief that "Having such thoughts must mean that deep down I am a bad person just waiting to surface."

The experience of the unhelpful metacognitive beliefs was closely related to Patrick's appraisals of over-responsibility. Patrick worked hard to rid himself of the intrusive thoughts because he believed that failing to do so would be irresponsible. The idea of hurting his family was the complete opposite of Patrick's "over-responsibility" values and part of the reason why he became so distressed by the intrusions. He catastrophized that if he lost control of his total functioning, he would not be able to look after his family and maintain his role as the responsible husband and father.

Finally, Patrick's temperamental tendency to want to do things perfectly resulted in continued stress and exhaustion at work. In a stressed and exhausted state, it was even harder for Patrick to cope with the intrusive thoughts. The stress and physical exhaustion were interpreted by Patrick as further evidence that he was losing control.

Patrick demonstrated behavioral avoidance of many different triggers to the unwanted thoughts and any experiences he considered a threat to his physical and mental equilibrium. For example, he completely avoided having alcohol, as he believed this would lead him to finally lose control. Patrick avoided sitting still—he kept himself occupied at all times so that he did not have time to think. At work he continually strove to complete tasks perfectly and at the same time tried to fill his mind with work matters to rid himself of the unwanted thoughts. Patrick avoided watching "unpleasant" television shows or reading newspaper articles or books describing violence or people who had "snapped" and

lashed out aggressively at others. As well as using the strategy of avoidance, Patrick replaced disturbing images of harming his family with positive images. He also occasionally sought reassurance by reading and rereading information on OCD.

Treatment Plan

Following collaborative consultation with Patrick's physician, a program of CBT with SSRI treatment (continued at the current medication dosage) was planned. This treatment approach is recommended in clinical practice guidelines and corresponds to step 4 of the stepped-care treatment model (Figure 16.1). CBT mapped well to the idiographic formulation of Patrick's OCD and was implemented to target the specified maintaining factors. These were (1) unhelpful appraisals of intrusive thoughts (e.g., over-importance of thoughts, thought-action fusion beliefs, catastrophic thinking), (2) cognitive avoidance and cognitive control strategies, and (3) behavioral avoidance.

Addressing over-importance of thought and thought-action beliefs. A major part of treatment attended to Patrick's unhelpful metacognitions. Psychoeducation explaining the influence of cognition on emotion was provided. An explanation of what intrusive thoughts are and how common they are in the general population was also provided. The clinician explained the Rachman and de Silva (1978) study, which demonstrated that nearly all of the general community experiences unwanted intrusive thoughts from time to time. Patrick was informed about the link between stress and the increased frequency of intrusive thoughts.

In-session experiments and demonstrations were used to help Patrick realize the counterproductive nature of his efforts to control his thoughts. For example, the "white bear" thought suppression exercise was used to show that trying hard not to have a thought only makes that thought occur more. Patrick was asked to practice sitting and simply observing his stream of thoughts without reacting or responding to them. This was set as homework practice in increasing time increments. Patrick started by simply trying to sit with his thoughts for 5 minutes and then gradually built up to periods of 40 minutes or more.

The therapist utilized Socratic questions to encourage Patrick to reevaluate the possibility that simply having a thought makes an event more likely. The therapist encouraged him to reconnect with his ability to reason in a scientific as opposed to a magical way. Short in-session exercises were used to illustrate points. For example, Patrick was encouraged to have the thought that his therapist would collapse before the end of the session.

Cognitive and behavioral avoidance. At first Patrick practiced simply sitting with his thoughts in session with the therapist, and then later the intrusive thoughts were purposely triggered in session. For example, the therapist brought in an article describing a violent attack and asked Patrick to read it. When the intrusive thoughts occurred, Patrick was simply instructed to observe the thought and make no attempt to get rid of it. Later, these kinds of exercises were assigned as homework.

An exposure hierarchy that provided a number of gradually challenging items was devised with Patrick. The therapist should always ensure that the first exposure exercise is very low on the client's Subjective Units of Distress Scale (SUDS). For example, an item rated 25 (out of 100) would be a good starting point. In the treatment of OCD it is essential that exposure be combined with response prevention. In other words, Patrick's usual rituals and avoidance strategies had to be removed. Patrick's exposure hierarchy is depicted in Exhibit 16.3.

Child Case

Andrew's parents were concerned that their 10-year old son's intense and frequent worry of robbers breaking into their home was worsening. The worries had an uneventful onset 10 months earlier, and their increasing frequency was causing significant disruptions to Andrew's life, including sleeping difficulties, a protracted bedtime routine, an impact on schooling due to tiredness, escalations in family conflict, social problems, and distress and irritability. Andrew described feeling concerned particularly at nighttime and reported that he needed to make sure that the family's belongings were secure, otherwise he was certain something bad would happen. He no longer held sleepovers at his house and was hesitant to attend sleepovers in case something bad happened while he was away from home.

Background to the Presenting Problem

Andrew was the second eldest of his siblings. He had two younger sisters ages 5 and 7, and an older sister age 11. There was a family history of anxiety and depression on his mother's side and the family had recently gone through some stressful events. Andrew's parents reported that Andrew had always had an anxious temperament.

Diagnosis and Assessment

Andrew and his parents attended separate clinical interviews and an ADIS-P was administered to his parents (see Exhibit 16.4).

16.3 | Patrick's Exposure Hierarchy

SUBJECTIVE UNITS OF DISTRESS SCALE RATING	EXPOSURE TASK
95	Read article about man who killed his entire family
90	Write sentence "I'm going to attack my family"
85	Drink full glass of wine with wife
70	Write the sentence "I'm going to lose my mind" on therapist's whiteboard—sit with the thought
65	Imagine biting off tongue in therapist's office without pushing the thought away
55	Sit at home for 15 minutes just observing thoughts
45	Watch the news
35	Have half a glass of wine at home with wife
25	Write the word "aggressive" on the whiteboard in therapist's office—do not try to push away any thoughts that occur in response

The therapist conducted a CY-BOCS interview with Andrew. The CY-BOCS checklist revealed that his obsessions were harm related and his compulsions were mainly checking and reassurance seeking. His list of nighttime rituals was exhaustive and included checking that the family's cars were locked, checking that the house doors were locked, closing curtains in the house, making sure robbers were not hiding in any parts of his bedroom or the house, closing his bedroom curtains, closing all the doors in the house, and repeatedly emerging from his room after bedtime to obtain reassurance from his parents that the doors were locked. His

Andrew's DSM Multiaxial Evaluation

Axis I	300.3	Obsessive-compulsive disorder
	300.4	Dysthymic disorder
Axis II		No diagnosis
Axis III		None
Axis IV		None
Axis V		Global assessment of functioning = 57, current

overall score on the CY-BOCS was 26; it was 11 on the obsessions scale and 15 on the compulsions scale.

Formulation

Predisposing factors. Andrew has a family history of anxiety and depression, which means that he may have a genetically conferred biological vulnerability to clinical anxiety. He has an anxious disposition, which means that it is likely that he has a general cognitive vulnerability to appraising information in a manner that leads to anxiety.

Precipitating factors. It emerged that Andrew's problems had developed after he heard a story about a break-in at the home of an extended family member. He began worrying that his family was unsafe and that his home was at risk of being broken into. He had also experienced some recent stressful events, and the stress-diathesis model suggests that inherent vulnerabilities to psychopathology may trigger clinical problems in the context of stressful life events.

Perpetuating factors. When Andrew experienced an intrusive and unpleasant thought about the possibility of a robber breaking into his home, he appeared to interpret the thought in a way that perpetuated his OCD symptoms. He overestimated the probability and severity of harm and overestimated his personal responsibility for reducing the potential danger. He demonstrated magical thinking in the form of thought-action fusion beliefs, believing that having thoughts about an unpleasant event meant that the event was going to happen. His compulsions perpetuated his anxiety by creating a false sense of safety and preventing an opportunity for unhelpful thoughts to be disconfirmed. Non-

occurrence of the feared event was falsely attributed to the compulsions. This increased the likelihood that the compulsion would be invoked as a strategy to alleviate distress in the context of future intrusive thoughts. His family accommodated his symptoms by assisting him with compulsions (e.g., they assisted him with repeatedly checking locks) and by providing reassurance in response to his reassurance-seeking behaviors (e.g., they reassured him that the doors were locked and that a robber would not break in). While this reassurance temporarily alleviated Andrew's anxiety, it is counterproductive in the long term, as it precludes opportunities for habituation to anxiety or helpful changes in thinking.

The predisposing, precipitating, and perpetuation factors are shown in Exhibit 16.5. It may be useful to share and refine this conceptualization in treatment with older adolescents, and with parents. Generating a shared understanding of the development and maintenance of a disorder may be a significant aspect of psychoeducation and may encourage commitment to and persistence with the treatment approach.

16.5

Andrew's Idiographic Case Formulation

Predisposing: Why did this happen to me?	■ Biological vulnerability
	■ Parental psychopathology
	■ Anxious disposition
Precipitating: Why did it happen now?	■ Vicarious frightening experience
	■ Recent stressful events
	■ Unhelpful appraisals of intrusive thoughts
Perpetuating: Why does it continue to happen?	■ Performance of rituals
	■ Behavioral avoidance
	■ Neurochemistry
	■ Family accommodation of symptoms
	■ Reassurance seeking

Treatment Course and Progress

Clinical practice guidelines recommend CBT as the appropriate first-line treatment for children with OCD. Andrew and his family commenced a course of therapy based upon March and Mulle's (1998) 12–20 week protocol. Joint parent and child sessions were held at sessions 1, 7, and 12, and all other sessions were individual child sessions. Treatment commenced with psychoeducation about OCD and cognitive restructuring. The problem was externalized and named “Worry Bucket” in order to unify the family and therapist in working toward a common goal, to reduce parental and child self-blame, to increase a sense of personal control, and to encourage a more optimistic focus. Some children, particularly younger children and those with a more recent onset or less severe symptomatology, respond powerfully to externalization strategies, and an invigoration of motivation and reduction in helplessness can be observed. Children may latch on to the inherent challenge of battling OCD (“Today I beat the Worry Bucket when I refused to check that the door was locked when it was telling me to”) and find it internally rewarding to have allies (parents and therapist) supporting them and sharing in their desire to manage OCD. If this is achieved, it is a critical phase of treatment and must be supplemented with effective strategies to alleviate the OCD symptoms (as opposed to the ineffective strategies that are usually perpetuating the disorder). The communicated expectation is that the child will gradually recover the “territory” claimed by OCD, with progress increasing in momentum as the child learns new strategies in therapy for his or her personal toolkit. It is important to take a graded approach to behavioral therapy (exposure) similar to what would be done with behavioral activation for depression, as tasks too high in difficulty that are presented early may overwhelm the patient and reinforce hopelessness. Optimistic children may become overconfident, as they can underestimate the difficulty of challenging OCD through behavioral tasks in terms of the level of anxiety aroused.

The second to fourth session of Andrew's treatment involved “mapping OCD,” or elucidating all obsessions and compulsions, and the anxiety level that would be experienced should associated compulsions not be performed. Anxiety was rated on a scale from 1 to 10 (called a fear thermometer). This allowed a hierarchy of tasks to be generated within an ERP paradigm. Sessions 5 and 6 and 8 to 10 were devoted to in-session ERP and cognitive therapy. In Andrew's case it was not possible to do in-vivo exposure in session, so imaginal exposure was undertaken. A major emphasis was placed on ERP homework activities, and Andrew and the therapist col-

laboratively planned daily ERP exercises that he could carry out over the coming week, beginning with the least anxiety-provoking items on Andrew's hierarchy (see Figure 16.2 to view SUDS ratings on sample exposure hierarchy items during the course of therapy). Homework activities were reviewed at the beginning of each session. At session 5 the CY-BOCS was readministered. His score was 17 on the global scale, 7 on the obsessions subscale, and 10 on the compulsions subscale, indicating that he was responding to CBT. Session 7 included his parents and the therapeutic rationale was revisited. Andrew and the therapist reviewed the different types of strategies he had learned and that had been placed in his toolkit, and the fear thermometer was reviewed for his parents, illustrating application during some of Andrew's ERP homework tasks. A major focus of this family session pertained to how OCD sneakily attempts to pull others into colluding with it, in order to take up more territory. Andrew and his parents were encouraged to consider if there was anything his parents did that might actually help out OCD and “make it stronger.” When parents and children do not identify examples of family accommodation when they are clearly present, it is useful for therapists to employ Socratic questioning techniques and prompting. In the session, scenarios of family accommodation were delineated as upcoming exposure tasks, and responses to reassurance seeking or requests for assistance with checking (should Andrew have difficulty refraining from compulsions) were modeled by the therapist.

Cognitive therapy techniques were used throughout the CBT program, beginning first with externalization of symptoms and with the planning of helpful self-talk when the Worry Bucket started to “boss” Andrew around. The therapist encouraged Andrew to practice helpful self-talk in and out of session when obsessions emerged. The therapist used cognitive therapy techniques during in-session exposures, purposefully teasing out anxiety-provoking thoughts in order to maximize anxiety habituation. The therapist consciously attempted to not provide Andrew with any reassurance throughout therapy.

- T: (During imaginal exposure) What are you thinking right now when you are in bed and you haven't checked that the door is locked?
- P: That a robber may be outside and that he may get into the house.
- T: There will always be a risk you are right (*no provision of reassurance*). I'd like you to sit with that feeling of anxiety for a little longer lying in bed

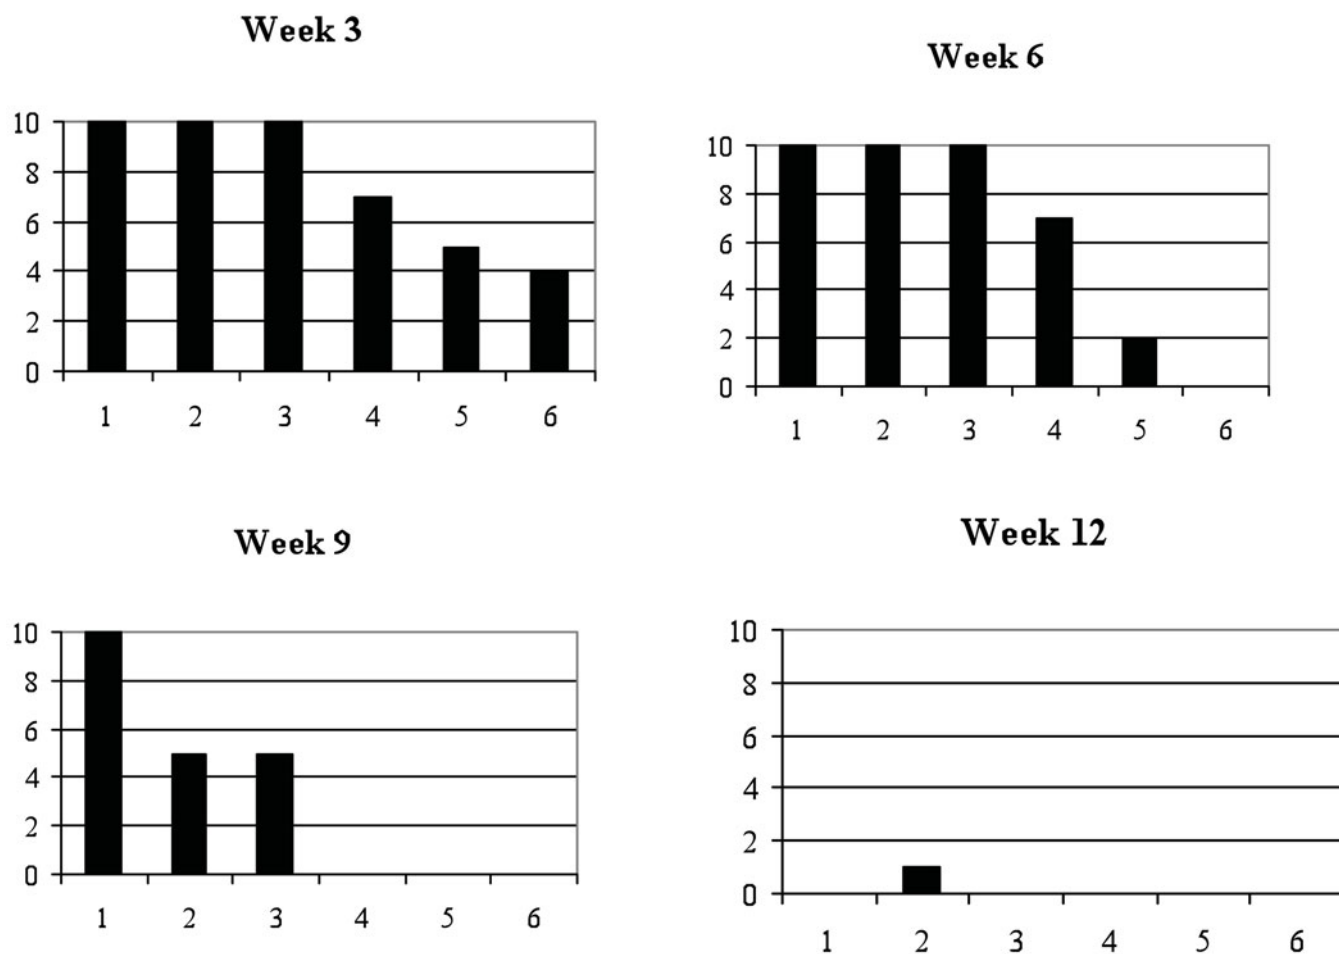

Figure 16.2 Subjective units of distress associated with performance of exposure tasks for a child at weeks 3, 6, 9, and 12 of CBT treatment.

thinking about the robber. Tell me more about what you are worrying about. . .

An important application of cognitive therapy techniques involves challenging unhelpful cognitive biases:

T: When you have the thought that a robber will break in, does OCD say it will happen 100% of the time, 50%, 10% . . . ?

P: 100%.

T: So if you haven't checked if the door is locked then there is a 100% chance of someone breaking in? (*overestimation of the probability of harm*) Do you think this is accurate?

P: No, because I might have locked the door earlier or Mom and Dad might have locked it. There might not be a robber outside anyway.

T: Ahh, because for a robber to break in there must be one outside. If there is not a robber outside then a break-in can't happen?

P: Right.

T: What does that tell you about what OCD is saying to you?

P: [pause]

T: Do you think that OCD could be trying to trick you?

P: I think that sometimes OCD is telling me something is true when it is not.

- T: So the Worry Bucket is passing his worries on to you. Instead of there being a 100% chance that the bad thing will happen . . . what chance would you guess there would be?
- P: Maybe 50% (*reduction in estimation of probability of harm*).
- T: What could you tell yourself to help make you stronger and OCD smaller when you have that thought that a robber will break in? (*encouragement of helpful self-talk*)
- P: That my worry goes away with time. I can tell myself that OCD is just trying to trick me and that I am stronger than it and that I can do the opposite of what it tells me and still be OK.
- T: That's right. We don't know what is going to happen in the future, but we do know that you can boss OCD back. What are some things in your toolkit that you can use to boss OCD back?

Challenging unhelpful cognitions, for instance, reducing the overestimation of the probability of harm, makes it likely that less distress will be experienced in the context of a triggering cognition. This can potentially break the vicious cycle of trigger thought → distress → compulsion → trigger thought, and so on. Combined, ERP and cognitive therapy strategies are potent methods for reducing the symptomatology of OCD.

The final sessions of a CBT program for OCD are aimed at relapse prevention. OCD is most likely to recur during periods of stress, and it is important for the child and family to brainstorm appropriate responses to re-emergences. In Andrew's case, post-treatment assessment at session 12 revealed that his OCD symptoms had declined to the normal range (CY-BOCS total score of 4, obsessions score of 2, compulsions score of 1), his depressive symptomatology had diminished, and he no longer met *DSM-IV* criteria for OCD. His treatment was considered to be complete. At 1-month telephone follow-up, treatment gains had been maintained. Had his symptoms persisted at a clinical level, it would have been appropriate to consider further treatment, such as an extension of CBT, further CBT combined with an SSRI, or an SSRI only. This decision would be clinically based and would take into consideration a number of factors.
